Abstract

The two-dimensional electron system (2DES) located at the surface of strontium titanate (STO) and at several other STO-based interfaces is an established platform for the study of novel physical phenomena since its discovery. Here we report how the interfacing of STO and tetracyanoquinodimethane (TCNQ), results in a charge transfer that depletes the number of free carriers at the STO surface, with a strong impact on its electronic structure. Our study paves the way for efficient tuning of the electronic properties, which promises novel applications in the framework of oxide/organic-based electronics.

Keywords: STO, TCNQ, charge transfer, orbital reorganization, conductivity

SrTiO₃ (STO) is a perovskite-type transition metal oxide, intensely studied due to its unique properties such as superconductivity¹ and ferroelectricity.²⁻⁴ The robustness and intriguing properties of a high-mobility electron gas at the interface between STO and LaAlO₃ (LAO),⁵ among others, has further fueled the research on various STO-based heterostructures.⁶⁻⁸ Similarly, at the surface of STO, a two-dimensional electron system (2DES) can be formed by irradiation with ultraviolet light⁹ or in-situ cleaving.¹⁰ To this end, it is of ultimate interest to explore different strategies to tune the 2DES properties, tailoring them for the various needs. A promising strategy is to add suitable adsorbates on the STO surface, exploiting the surface nature of the 2DES. Oxygen-deficient STO thin films show high conductivity variation in response to the oxygen^{11,12} or ethanol¹³ concentration of the gas they are in contact with. Similarly, hydrogen adsorption on the surface is reported to have a surface doping effect, with a metallic state appearing at the Fermi level¹⁴ equivalent to n-doping.¹⁵ In an analogous way, it has been shown that the protonation state of the LAO surface has a dramatic impact on the conductivity at the LAO/STO interface.^{16,17}

In order to achieve less volatile devices, molecular building blocks commonly used in organic electronics and spintronics heterostructures are advantageous. The resulting organic-oxide interfaces exhibit a huge variability arising from the vast number of combinations of the two constituents. They allow to exploit the chemical functionalization¹⁸ and the multifunctionality of molecules,¹⁹ which were proven useful in spin valves²⁰ and photoswitchable logic.²¹

In this work, we investigate the effect of adsorption of the organic electron acceptor tetracyanoquinodimethane (TCNQ) on the electronic properties of the vacuum-annealed STO surface. We show through *in-situ* electrical transport and synchrotron-based near-edge X-ray absorption fine structure (NEXAFS) measurements that the molecular adsorption results in a charge transfer from the STO surface to the TCNQ layer. This is followed by a reorganization of the Ti 3d orbitals at the STO surface, as proven by X-ray absorption

spectroscopy (XAS) as well as by resonant and non-resonant photoemission spectroscopy (ResPES and PES).

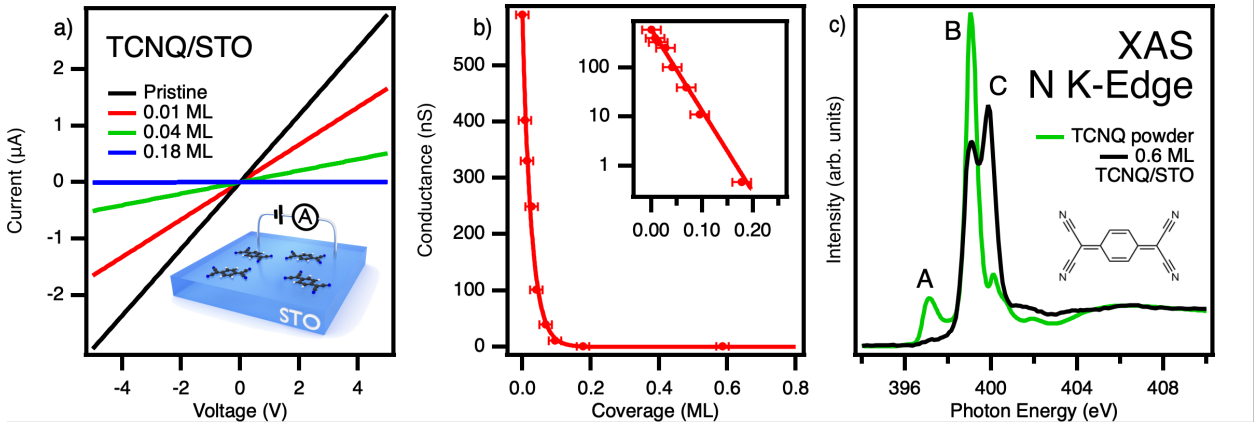

Figure 1: Electrical properties of the TCNQ/STO interface and adsorption behavior of TCNQ. **a**, The $I(V)$ characteristics of STO(100) as a function of TCNQ coverage. **b**, The evolution of conductance as a function of molecular coverage in units of molecular monolayers (MLs). Symbols and the solid line denote experimental data and the best-fit curve, respectively, as explained in the text. The inset contains the same data in a semi-logarithmic scale. Measurements were performed in an ultra-high vacuum at room temperature. **c**, Nitrogen K-edge NEXAFS obtained on a TCNQ powder sample (green curve) and on a 0.6 ML TCNQ/STO interface (the latter one obtained at the magic angle - see methods). In the inset, a ball-and-stick representation of the TCNQ molecule, with the central benzene backbone and the four cyano groups on the sides is shown.

Fig. 1a displays the $I(V)$ characteristics obtained for the vacuum-annealed (500 °C, 30 minutes - hereinafter denoted as pristine) STO and for different coverages of TCNQ, which was sublimed from a Knudsen cell, on STO. All samples exhibit ohmic $I(V)$ behavior as manifested in the linear $I(V)$, however, upon deposition of TCNQ, the conductance drops dramatically. Note that the conductance of the pristine sample may include a contribution from the contact resistance of the bond wires. However, for TCNQ coverages larger than a few percent of the STO surface the effect of the contact resistance, which is independent of the TCNQ coverage, becomes negligible. The corresponding coverage-dependent conductance values extracted from the $I(V)$ measurements are plotted in Fig. 1b, revealing that the electrical conductance drops by more than three orders of magnitude from 600 nS of the pristine STO down to 0.5 nS upon deposition of only 0.18 monolayers (MLs) of TCNQ.

Here, a ML is defined as a densely packed layer of molecules in flat adsorption geometry. A sub-ML denotes a partial molecular coverage with molecules with uncovered portions. Fig. 1b reveals that at low coverages the conductance σ depends exponentially on the TCNQ coverage x (in units of MLs) $\sigma(x) = \sigma_0 e^{-R_0 x}$, where σ_0 is the conductance of the annealed STO before deposition and R_0 contains the coverage dependence. Fitting yields a remarkably large value of $R_0 = 38 \pm 4.3 \text{ ML}^{-1}$ reflecting the enormous coverage dependence of the surface conductance and $\sigma_0 = 590.1 \pm 0.1 \text{ nS}$. Note that the strong dependence on the molecular coverage confirms that the observed change in conductance takes place at the TCNQ/STO interface. Two factors may lead to the reduction of the conductance at the STO surface: i) the reduction of the charge carrier mobility or ii) the reduction of the number of charge carriers contributing to the electrical transport. Below, we will demonstrate that the second mechanism is the main driving force, owing to a charge transfer from the surface of STO to the electron-accepting molecules, with the effect of depleting the number of carriers responsible for the surface conductivity.

The NEXAFS at the nitrogen K-edge displayed in Fig. 1c supports this hypothesis: the TCNQ powder spectrum shows three main resonances at photon energies of (A) 397.4 eV, (B) 399.1 eV and (C) 399.9 eV. Peak (A) corresponds to the π^* lowest unoccupied molecular orbital (LUMO), mostly localized on the benzene backbone, while peaks (B) and (C) originate from σ^* and π^* symmetry molecular orbitals localized on the cyano groups.²² Molecules adsorbed on the STO surface, however, hardly display any trace of the LUMO resonance: its quenching is characteristic of negatively charged TCNQ⁻¹ molecules having an aromatic central ring,²²⁻²⁵ confirming the electron transfer to the molecules from the substrate.

A charge transfer across the interface must have an influence also on the 2DES and on the electronic structure of the surface of STO. Fig. 2a-c displays coverage-dependent PES, showing the evolution of the photoemission peaks of the substrate. All of them exhibit an attenuation of the total intensity and a peak shift toward lower binding energy upon increasing TCNQ coverage.

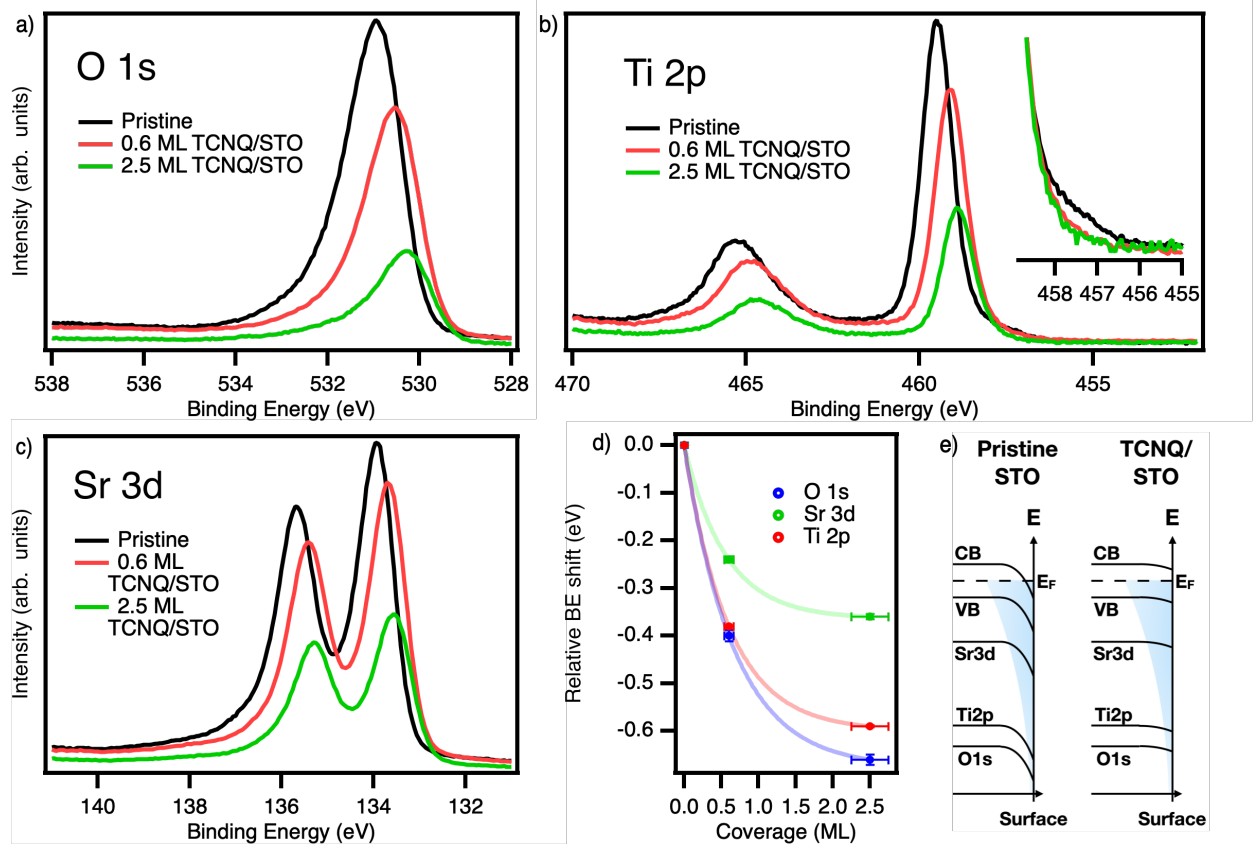

Figure 2: **Coverage dependent PES reveals lowering of binding energy and band flattening.** a, O 1s peak, b, Ti 2p peak, c, Sr 3d peak. In the inset of panel b, the region of the Ti^{3+} peak: in this case, all peaks have been aligned and normalized to the pristine one. All spectra have been acquired at room temperature and at a photon energy of $h\nu = 650$ eV. d, Relative binding energy shift as a function of TCNQ coverage, lines are guides for the eye. e, Scheme of the band bending (not to scale) occurring at the surface of bare annealed STO (left) and TCNQ/STO (right). The cyan shadowed region is the one photoemission is sensitive to.

The intensity decrease is due to the inelastic scattering of photoelectrons crossing the molecular overlayer, and its magnitude is kinetic energy dependent: the higher the electron kinetic energy (hence, the lower the binding energy), the less pronounced this effect is. The same tendency is also observed for the binding energy shift: the higher the binding energy, the more pronounced the shift, as visible in Fig. 2d. This similarity suggests that the binding energy shift is depth-dependent, which is consistent with a lowering of the band bending which is present on the pristine STO surface, as illustrated in Fig. 2e.

Bulk STO is a wide band-gap ($\Delta_{\text{gap}} = 3.2$ eV) semiconductor²⁶ with the Fermi level close

to the conduction band (CB) minimum.^{14,27–29} While in bulk stoichiometric STO no surface state was found, resulting in negligibly small band bending at the surface,³⁰ annealing in UHV at 300°C for several hours results in a conducting surface.³¹ This accumulation of negative charges at the surface, together with the downward band bending³² corresponds to the case of surface n-doping as shown in Fig. 2e. Upon TCNQ adsorption, the charge transfer across the interface depletes the 2DES, with the effect of flattening the bands as illustrated in Fig. 2e. In the case of the deep core levels such as O 1s and Ti 2p the photoelectrons originate from the very surface of STO, where the effect of band movement upon charge depletion is strongest. On the other hand, the photoelectrons coming from the Sr 3d core level travel from the surface but also from a slightly deeper region in bulk (as highlighted by the cyan region in Fig. 2e), where the effect of surface band bending is weaker.

Photoemission results also yield specific information about the oxidation state of the Ti ions in STO. The inset of Fig. 2b shows the low binding energy region of the Ti 2p_{3/2} peak. Here, all peaks in the graph have been aligned to the ones of the pristine sample and normalized to the same height. The pristine spectrum obtained on pristine STO shows a shoulder at $E_B = 457.3$ eV, which is commonly associated with the presence of Ti³⁺ species in STO. Like in the case of reduced TiO₂, the presence of the Ti³⁺ shoulder is always accompanied by the appearance of in-gap states due to the partial filling of the Ti 3d unoccupied states.^{33–36} The Ti³⁺ shoulder disappears completely upon TCNQ deposition, at both coverages of 0.6 and 2.5 MLs, indicating a surface containing only Ti⁴⁺ species. Tracking the corresponding behavior of the in-gap states upon TCNQ deposition, however, is not straightforward because of the possible overlap of the TCNQ highest occupied molecular orbital (HOMO) and filled LUMO states in this energy region.³⁷

In order to disentangle the in-gap states at the STO surface from the contributions of the molecular orbitals, we used core-hole assisted resonant photoemission, i.e. measure the valence band photoemission at incoming photon energies resonant with the Ti L₃-edge. In this case, predominantly the spectral features associated with states having contributions

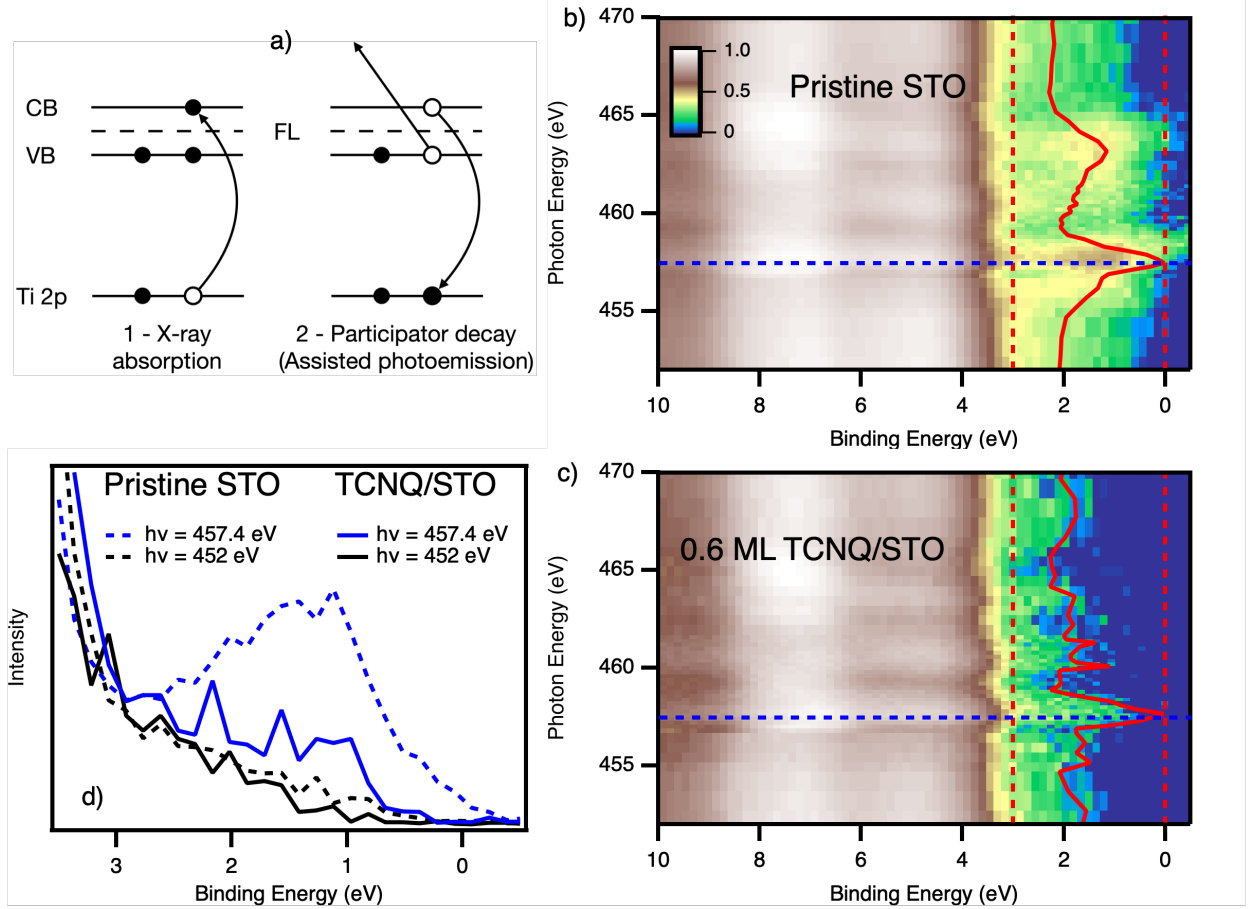

Figure 3: **Resonant photoemission.** **a**, Schematic of the core hole-assisted photoemission process. **b** and **c**, valence band intensity maps across the Ti $L_{2,3}$ -edges for pristine STO and 0.6 ML TCNQ/STO interface respectively (color code in the inset): the red curve are the CIS integrated over the in-gap states (exact regions marked with dashed lines of the same color). **d**, Single valence band spectra acquired at notable photon energies: $h\nu = 452$ eV (off-resonance) in black, $h\nu = 457.4$ eV (highest resonance in both CISs) in blue.

from Ti 3d orbitals are excited and thus enhanced,³⁸ due to the very short range of the mechanism of excitation decay (Auger process).³⁹ Figure 3a shows the schematics of this process: a photon resonant with the core-level \rightarrow conduction band transition excites the system, which then decays following (among the others) the depicted participator decay, whose final state is equivalent to the one of the direct photoemission, but with several orders of magnitude higher cross-section. In Fig. 3b,c we report the valence band photoemission spectra on pristine STO and 0.6 ML TCNQ/STO as a function of the incoming photon energy. The intensity variation of the binding energy region integrated in the range 0-3 eV

is overplotted as a red line in the 2D color maps. This profile, called constant initial state (CIS), gives information on the response to different excitation energies of the photoemission yield of specific states, in this case, the region containing the in-gap states. Both in pristine STO and in 0.6ML TCNQ/STO cases, the CIS shows a resonance at $E_{\text{phot}} = 457.4$ eV, corresponding to the Ti $2p_{3/2} \rightarrow 3d t_{2g}$ transition.

The strong CIS resonance at the blue dotted line and the tail extending up to the Fermi level highlights the presence of the in-gap states. Fig. 3d displays horizontal cuts of the maps along the blue dotted lines in Fig. 3b,c in the range of $E_B = 0 \dots 3$ eV at the photon energies indicated in the plot. In both cases, the photoemission intensity in the in-gap region is enhanced across the resonance: the area under the spectrum in the region $0 \dots 3$ eV of binding energy increases by a factor $\times 3.4$ at $E_{\text{phot}} = 457.4$ eV with respect to the off-resonance spectrum. In the case of the 0.6 ML TCNQ/STO, however, the in-gap region shows negligible intensity enhancement: the blue spectrum shows an increase of the area in the region $0 \dots 3$ eV of a factor $\times 1.6$, that is less than halved with respect to the pristine STO case (47%).

Taking into account only the attenuation of the photoemission intensity due to the TCNQ molecules using Lambert-Beer’s law, an intensity drop down to 85% would be expected. Therefore, the observed drop down to 47% implies that the photoemission intensity is strongly reduced upon TCNQ adsorption. This spectral weight reduction points to a depopulation of the in-gap states due to an electron transfer from the substrate into the TCNQ molecular orbitals, like formerly demonstrated for the quenching of the $\text{TiO}_2(110)$ defect state by adsorption of perylene-tetracarboxylic-diimide,³⁸ as well as for $\text{C}_{60}/\text{TiO}_x$.⁴⁰

Finally, it is worth taking into consideration the surface stoichiometry of the STO surface. Although it has been shown that even a moderate thermal treatment can result in the presence of different surface terminations,⁴¹ this does not have an influence on the results and conclusions drawn in the present work. Moreover, TCNQ itself does not contain oxygen atoms, therefore the disappearance of the Ti^{3+} peak and in-gap states cannot be related to

any filling of oxygen vacancies, and it must be ascribed exclusively to the transfer of charges occurring across the interface.

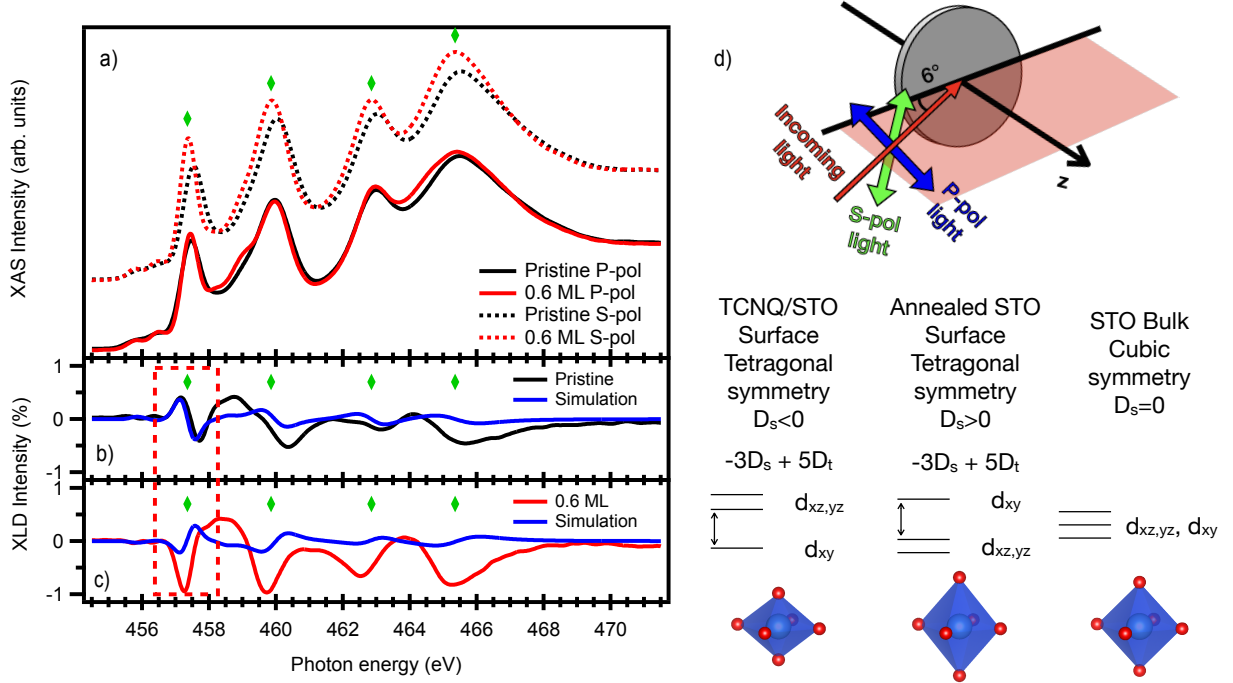

Figure 4: **X-ray linear dichroism at the Ti $L_{2,3}$ -edges.** **a**, XAS acquired in partial electron yield with S-polarized (solid lines) and P-polarized light (dashed lines) for the pristine (black lines) and TCNQ-deposited (red lines) samples. Panels **b** and **c** show the corresponding XLD spectra. The blue lines represent calculated XLD spectra with $D_s < 0$ and $D_s > 0$, respectively for the TCNQ/STO and pristine STO samples. Panel **d** sketches the experimental geometry (top) and the different crystal distortions giving rise to the calculated spectra.

Like photoemission, Ti L-edge XAS and X-ray linear dichroism (XLD) are excellent tools to compare the electronic structure changes between the TCNQ/STO interface and pristine STO. Fig. 4a shows the XAS acquired in S and P polarization of 0.6 ML TCNQ/STO and pristine STO, with the corresponding XLDs shown in panels **b** and **c**. Upon molecular adsorption, the XLD signal in the region between 458 eV and 460 eV (corresponding to the Ti $2p_{3/2} \rightarrow 3d t_{2g}$ transition - highlighted by a red box in the figure) is reversed, as already

observed in STO upon LAO coverage⁴² Multiplet calculations shown in panels **b** and **c** can qualitatively describe this behavior by breaking the cubic symmetry of the bulk and reversing the sign of D_s from +20 meV in the annealed case,^{43,44} to -20 meV after deposition of TCNQ. The D_s parameter in the calculations corresponds to the energy splitting between the in-plane and out-of-plane orbitals in the t_{2g} manifold, and its change of sign indicates an orbital reorganization at the STO surface upon molecular adsorption. In the pristine sample the $d_{xz/yz}$ orbitals are the lowest-energy state, while after deposition, the d_{xy} orbital become the lowest, as highlighted in Fig. 4d. More details can be found in the Supplementary Information. The orbital reorganization may be due to molecule-substrate hybridization and the subsequent modification of the effective crystal field,¹⁵ and/or structural distortions at the STO surface that have been shown to have a profound impact on the properties of the 2DES at the surface of STO.⁴⁵

In conclusion, we have combined *in-situ* electronic transport, X-ray absorption spectroscopy, and (resonant) photoemission to study the impact of the adsorption of TCNQ on the electronic properties and the surface conductance of $\text{SrTiO}_3(100)$. The adsorption of a sub-monolayer amount of TCNQ on STO leads to a massive suppression of the electrical conductance at the STO surface by several orders of magnitude. Nitrogen K-edge absorption spectra reveal that this effect arises from a charge transfer from the substrate toward the molecules, while core-level photoemission evidenced that this charge transfer reduces the band bending at the surface. Also, upon charge transfer Ti^{3+} ions at the STO surface are converted into Ti^{4+} ones, and the in-gap states of STO are depleted. X-ray absorption spectroscopy reveals a change from compressed toward elongated oxygen octahedra surrounding the Ti ions upon TCNQ adsorption, which implies a re-ordering of the Ti 3d orbitals.

We emphasize that these effects are stable at room temperature because of the non-volatility of the organic molecules used. One way to create nanodevices could be by the controlled, local deposition of organic molecules to write features onto the oxide surface, which would allow for a dramatic improvement of the minimum feature size compared to

state-of-the-art lithography techniques. We demonstrate a new class of hybrid organic-oxide materials appealing for devices, sensors, and energy-related applications. The versatility, chemical tunability, and multifunctionality of oxide and molecular materials give rise to an impressive potential for future applications. These include the use of molecular units with different electron accepting or donating properties and the exploitation of other multifunctional building blocks such as photoactive units exhibiting intramolecular charge transfer.

Methods

Substrate preparation - The TiO_2 -terminated undoped STO(100) (SurfaceNet GmbH, Germany) of dimensions $4.8 \times 5 \text{ mm}^2$, thickness 0.5 mm, one-side polished, was wedge bonded prior to the experiment and introduced into ultra-high vacuum ($p \sim 10^{-10} \text{ mbar}$). The separation between the leads at the STO surface was $4.5 \pm 0.2 \text{ mm}$. STO was annealed at 773 K for 30 minutes to remove contamination and to prepare atomically flat terraces.⁴⁶ The annealed STO surface was checked by low energy electron diffraction (LEED), exhibiting the expected 1×1 pattern (see Supplementary Figure S2).³¹ A similar but Nb-doped substrate was prepared in an analogous manner with and without TCNQ and checked by scanning tunneling microscopy (see Supplementary Information). The sample preparation and the electrical transport measurements were performed within the same ultra-high vacuum environment of the X-Treme beamline at the Swiss Light Source, Paul Scherrer Institut⁴⁷ in the absence of X-rays.

Molecule deposition - TCNQ was sublimed in ultra-high vacuum ($p \sim 10^{-10} \text{ mbar}$) from a Knudsen cell held at 368 K resulting in low deposition rates (0.04–0.1 monolayers/min) onto the substrate held at room temperature. The deposition rates were determined using a quartz crystal microbalance.

Electrical transport measurements - The conductance of the STO surface was measured using two wedge-bonded contacts in ultra-high vacuum and at room temperature. The

two-point measurement, as opposed to more sophisticated (e.g. van der Pauw like) schemes, is sufficient here because of the significant initial and further increasing (upon molecule deposition) resistance of the STO surface, rendering the resistance of the wires and contacts negligible. The conductance was calculated from the slope of the $I(V)$ characteristics acquired using a Keithley 6517B sourcemeter. The error bars are within the symbol size.

X-ray spectroscopy - XAS at the Ti L-edges and the N K-edge were performed at room temperature in partial electron yield mode (PEY) at the ALOISA beamline at Elettra.⁴⁸ A manipulator collinear with horizontally polarized synchrotron light rotates around its axis to change the geometry from S- to P-polarization while the angle of incidence of light is fixed to 6 degrees. The XLD was calculated as $\mu^P - \mu^S$, where μ^i are the corresponding absorption spectra for the two linear polarizations.

Photoemission spectroscopy - All measurements were performed at room temperature at the ALOISA beamline at Elettra⁴⁸ using 0.5% wt Nb:STO as substrate. Electrons were collected using a hemispherical analyzer at normal emission, while the angle of incidence of light was kept at 4 degrees. 0.6 ML TCNQ/STO did not show any sign of degradation under the beam, while 2.5 ML TCNQ/STO showed a slow degradation, which was mediated by illuminating different spots on the surface.

Ligand-field multiplet calculations - The Ti $L_{2,3}$ XAS were simulated using multiplet calculations, including ligand field effects, using the CTM4XAS interface.^{49,50} Details and best-fit parameters are given in the caption of Fig. S1 of the Supporting Information.

TOC Graphic

Some journals require a graphical entry for the Table of Contents. This should be laid out “print ready” so that the sizing of the text is correct. Inside the tocentry environment, the font used is Helvetica 8 pt, as required by *Journal of the American Chemical Society*.

The surrounding frame is 9 cm by 3.5 cm, which is the maximum permitted for *Journal of the American Chemical Society* graphical table of content entries. The box will not resize if the content is too big: instead it will overflow the edge of the box.

This box and the associated title will always be printed on a separate page at the end of the document.

SUPPLEMENTARY INFORMATION

Charge transfer and orbital reconstruction at an organic-oxide interface

1 Supplementary ligand-field multiplet calculations

Figure S1. Supplementary plots showing simulated XLD (calculated as $\mu^P\text{-}\mu^S$ for 0° incidence angle) spectra using the parameters given in the plots. (a-c) show that the changes observed experimentally in the XLD cannot be reproduced by a change in other parameters except of changing the sign of D_s . (d) shows that the trend cannot be reproduced with a linear combination of Ti^{3+} and Ti^{4+} . (e) shows that many values of D_t can reproduce the experimental spectra, such that it could not be fully determined. All values are given in units of [eV]. Charge transfer effects are included by expanding the initial state $2p^63d^n$ beyond the ionic approximation in $2p^63d^{n+1}\underline{L}$, where \underline{L} denotes an O 2p hole. The parameters used are the charge transfer energy $\Delta = 4$ eV, the Mott-Hubbard repulsion $U = 3$ eV, and the Ti 3d-O 2p hybridization T_σ [1], detailed below. The Ti 2p core-hole potential is included via the parameter $Q = U/0.83$ [2]. The Slater integrals were reduced to 90% of their original values. The splitting of the d levels into t_{2g} and e_g subbands is controlled by the mean value of the crystal field $10Dq = 2.2$ eV, while in D_{4h} symmetry, each subband is further split by $D_t = \pm 2$ meV and $D_s = \pm 20$ meV into b_1, a_1, b_2 and e levels. The transfer integrals were close to 2 eV for the b_1 and a_1 ($d_{x^2-y^2}, d_{z^2}$) orbitals, and 1 eV for the b_2 and e ($d_{xy}, d_{xz/dyz}$) orbitals, respectively. The calculated spectra were broadened with Gaussian functions with 0.1 eV FWHM to simulate the experimental resolution and Lorentzian functions with FWHM of 0.1 eV, 0.5 eV, 0.5 eV and 1.0 eV, respectively, for the transitions to the b_1, a_1, b_2 and e levels [3]. The calculated spectra were shifted in energy and the parameters were adjusted to best match the experimental data.

2 Low energy electron diffraction of the bare, annealed STO surface

Figure S2. Low energy electron diffraction (LEED) image recorded on the bare annealed STO surface at an electron energy of $E_{\text{el}} = 316$ eV. The LEED shows the 1×1 pattern as expected from previous studies [4] for similar preparation conditions.

Figure S3. (a) STM micrograph (200×200 nm²) of the bare, annealed Nb:STO surface. Bias voltage +2 V, current setpoint 2 pA. (b) STM micrograph (200×200 nm²) of 1 ML TCNQ / Nb:STO. Bias voltage +2 V, current setpoint 2 pA. Inset in (b): Self-assembled TCNQ molecules on Cu(111). 12×12 nm², bias voltage -1 V, current setpoint 10 pA.

The scanning tunneling microscopy (STM) was performed at the PEARL beamline of the Swiss Light Source [5] by means of an Omicron LT-STM at 4.3 K in ultra-high vacuum ($p \leq 10^{-10}$ mbar). Nb-doped (0.5-%) TiO_2 -terminated $\text{SrTiO}_3(100)$ (SurfaceNet GmbH, Germany, lateral dimensions

$5 \times 5 \text{ mm}^2$, thickness 0.5 mm, one-side polished) was used as a substrate. The Nb-doped STO sample was prepared by thermal annealing in ultra-high vacuum up to 988 K. The TCNQ molecules were evaporated during one minute ($p \leq 10^{-9}$ mbar) from a glass crucible held at 358 K onto the substrate at room temperature. In order to check the TCNQ deposition, a Cu(111) single crystal surface was prepared by repeated cycles of Ar^+ ion sputtering and annealing. Depositions were performed under the same conditions in order to compare the behaviour of TCNQ on copper and on STO.

Fig. S3a shows an STM micrograph recorded on the bare STO surface after annealing. The wide terraces show a corrugation of $1.3 \pm 0.2 \text{ \AA}$ (except for steps). Furthermore, the height of the step edge visible in the Figure is $3.7 \pm 0.2 \text{ \AA}$, consistent with former studies [3], indicating the quality of the samples. Fig. S3b shows the same STO surface after TCNQ deposition. No clear signatures of the TCNQ molecules are visible, neither in STM images taken at a smaller length scale suggesting that the molecules are still mobile under the STM tip even at low temperature. Nevertheless, one can distinguish terraces suggesting that the molecules are adsorbed as a homogeneous layer. The inset of Fig. S3b displays an STM micrograph of TCNQ molecules adsorbed on Cu(111). They appear as oval shapes of size $12.6 \pm 0.5 \text{ \AA}$ by $8.0 \pm 0.5 \text{ \AA}$ with an apparent height of $1.0 \pm 0.1 \text{ \AA}$. Taking into account these lateral sizes and the fact that TCNQ/Cu(111) tends to form multiple different self-assembled patterns supports the quality of the sample preparation [6].
