ABSTRACT

The modification of natural zeolites via ion exchange is an efficient technique used to improve their performances and tune their properties for specific applications. In this study, a natural levyne-Ca intergrown with erionite was fully exchanged by Ag⁺ and its structure [with idealized chemical composition Ag₆(Si,Al)₁₈O₃₆·18H₂O] was investigated by combining a theoretical and experimental approach. Single-crystal X-ray diffraction data demonstrated that Ag-levyne maintained the $R\bar{3}m$ space group, characteristic of the natural levyne. Ag ions distribute over partially occupied sites along the threefold axis and, differently from the pristine material, at the wall of the 8-membered ring window of the *lev* cavity. The lack of ~30% of Ag ions that could not be located by the structural refinement is ascribed to the strong disorder of the extraframework occupants. The structural results obtained by Molecular Dynamics simulations are in overall agreement with the experimental data and showed that, on average, Ag⁺ is surrounded by ~2 H₂O and 1 framework oxygen at distances between 2.43 and 2.6 Å. Molecular Dynamics trajectories indicate that the occurrence of silver inside the D6R cage depends on the water content: silver occupancy of D6R cages is estimated to be 83, 30, and 0% when the structure contains 3, 2.5, and 2 H₂O per Ag ion, respectively.

The cation-exchange process, as demonstrated by scanning electron microscopy and energy-dispersive spectroscopy (SEM-EDS) spectrometry, affects the intergrown erionite as well. A structural characterization of the Ag-erionite phase (with dimension <100 µm) was possible by means of a CuKα micro-focus source: structure solution pointed to $P6_3/mmc$ space group, indicating no change with respect to natural erionite. In agreement with previous studies, K ions in the cancrinite cage could not be exchanged, whereas Ag⁺ is found in the *eri* cavity.

INTRODUCTION

The mineral series levyne, comprising levyne-Ca and levyne-Na, belongs to the zeolites group. The crystal structure of these minerals is described by a three-dimensional aluminosilicate tetrahedral framework in which charge compensating alkali and/or alkaline earth cations and H₂O occupy the structural voids. Due to their microporous structure, zeolite minerals show interesting properties such as cation exchange, adsorption, reversible hydration/dehydration and the capacity of acting as molecular sieves (Bish and Ming 2001). For this reason, they are successfully applied for a broad range of applications, and, in particular, in environmental remediation processes (treatment of radioactive wastewater and remediation of contaminated sites) (Colella 1999; Babel and Kurniawan 2003; Borai et al. 2009; Misaelides 2011; Wang and Peng 2010). Compared to their synthetic counterpart, natural zeolites typically show greater thermal stability and better resistance to acid environments (Ackley et al. 2003). Rich opportunities for technological applications, abundance in nature, and low mining costs motivates research on structural and chemical

properties of natural zeolites in various scientific disciplines.

LEV-type zeolites are of interest because, despite their small pore openings, they show large micropore volume (0.3 cm³/g) (Yamamoto et al. 2010). Thus, several phases with LEV topology have also been synthesized (Flanigen et al. 1986; Lock et al. 1984; Zhu et al. 1997) and Ca-LEV was suggested as potential hydrogen-storage medium (Liang et al. 2012).

The naturally occurring levyne belongs to the so-called ABC-6 family of natural zeolites (Gottardi and Galli 1985). The LEV framework type of levyne is characterized by a sequence of single six-membered rings (6mR) and double six-membered rings (D6R) of tetrahedra stacked along the *c* axis following the AABCCABBCAA sequence. This sequence originates columns along [001] of cavities [4⁶5⁸3] (*lev* cavity), which alternates with double six-ring [4⁶6²] polyhedra. Two dimensionally interconnected channels confined by eight-membered rings run perpendicular to [001]. The crystal structure at room temperature is described in $R\bar{3}m$ space group (Merlino et al. 1975; Sacerdoti 1996). Natural crystals of levyne are often twinned by 180° rotation along the *c* axis simulating $P6/mmm$ symmetry (Sacerdoti 1996). Moreover, intergrowths with erionite/offretite, two other zeolites pertaining to the ABC-6 family, have been frequently reported in natural occurring levyne (Shimazu and Mizota 1972;

* E-mail: georgia.cametti@krist.unibe.ch. ORCID 0000-0002-3186-3074

† Special collection papers can be found online at <http://www.minsocam.org/MSA/AmMin/special-collections.html>.

Bennett and Grose 1978; Wise and Tschernich 1976; Passaglia et al. 1974).

The microporous properties of natural zeolites are controlled by the extraframework (EF) cations content. The modification of their crystal-structure via cation exchange has been proven to improve their performances over a wide range of applications (Kasture et al. 1998; Ackley et al. 2003; Kanazawa 2004; Zukal et al. 2010; Amooghin et al. 2016; Ma et al. 2018; Abreu et al. 2019). In particular, Ag-exchanged zeolites show increased sorption and photocatalytic capacity (Hutson et al. 2000; Coutino-Gonzales et al. 2015) and antibacterial efficacy (Milenkovic et al. 2017; Ferreira et al. 2012). To predict the zeolites behavior in terms of stability and microporous properties two factors are particularly important: (1) the position of the EF cations in relation to the aluminosilicate framework, and (2) the modification of the framework itself as a consequence of the EF cations substitution.

In this study, we investigate the crystal structure of Ag-levyne produced by cation exchange of a natural levyne-Ca. To determine the EF cation arrangement in the zeolitic channels and to have a better insight into the local environment of silver atoms and global structural disorder, we combined an experimental and theoretical approach. The average structural parameters were determined by means of single-crystal X-ray diffraction and compared with that obtained by Molecular Dynamics simulations. Moreover, a detailed structural characterization of the erionite intergrowths was also undertaken.

MATERIALS AND METHODS

The sample used as starting material was a natural levyne with chemical composition $\text{Ca}_{2.53}\text{Na}_{0.72}\text{K}_{0.23}(\text{Al}_{5.36}\text{Si}_{11.8}\text{O}_{36}) \cdot 17.5\text{H}_2\text{O}$ from Beech Creek, Oregon, U.S.A. The crystals were selected from the same specimen (sample number A7827 of Natural History Museum of Bern) used by Cametti (2018).

The exchange experiments were performed following two steps: at first, levyne crystals with dimensions ranging from 0.08 and 0.3 mm were treated for four weeks with 1 M NaCl solution at 100(2)°C in a Teflon (polytetrafluoroethylene) autoclave. The solution was renewed every three days. Afterward, the Na-exchanged crystals were equilibrated with a 2 M AgNO_3 solution (pH = 5–6) at 100(2) °C for five weeks. For this second exchange-step, the crystals were also located in a Teflon autoclave and darkness conditions were maintained during the whole experiment. The AgNO_3 solution was periodically renewed every three days. The crystals were subsequently removed from the autoclave, washed with deionized water and analyzed by energy-dispersive spectrometry (EDS) using a ZEISS EVO50 scanning electron microscope (SEM) to ensure the completeness of the exchange process. Operating conditions were 20 kV accelerating voltage, 10 mm working distance, 30 s acquisition time. An attempt to analyze the same samples with electron microprobe was not successful due to the small crystal size. Final chemical composition was calculated on the basis of 36 O after renormalization of the chemical analyses hypothesizing a water content of 18 wt%.

Single-crystal X-ray diffraction (SCXRD)

Diffraction data were collected on a Bruker APEX II diffractometer equipped with a $\text{MoK}\alpha$ source ($\lambda = 0.71073$) and a CCD detector. A single crystal of Ag-levyne with dimension $0.180 \times 0.150 \times 0.100$ mm was glued on the tip of a glass fiber and mounted on a goniometer head.

The unit-cell determination indicated a rhombohedral Bravais-lattice. An inspection of the reciprocal lattice pointed out the presence of an additional set of reflections (~6–7% of the total ones) that could be indexed with the same rhombohedral unit cell rotated by 180° with respect to the *c*-axis. The data were integrated and corrected for absorption by using the Apex 3v.2018.7-2 software package (Bruker 2019).

The structure was solved in space group $R\bar{3}m$ by direct methods using SHELXTL-2008 (Sheldrick 2008). Structural refinement was carried out by SHELXL-2014 (Sheldrick 2015) by using neutral atomic scattering factors. Starting coordinates and atomic labels of framework atoms were those reported

in Sacerdoti (1996), whereas the EF cations and H_2O molecules were located by difference Fourier maps. The obverse-reverse twinning $[100\ 010\ 001]$ was refined with fractional volume contribution of 0.058(4).

Erionite and offretite intergrowths have been frequently reported for levyne specimen from the same locality (Bennett and Grose 1978; Passaglia et al. 1998; Cametti 2018). SEM-BSD pictures of our sample showed the occurrence of another fibrous-mineral phase intergrown between levyne crystals (Fig. 1). To find out whether the intergrown mineral was erionite or offretite and to determine how this phase was affected by the exchange experiments, single fragments of secondary phase were extracted to perform subsequent structural analyses. Fragments of Ag-exchange levyne were at first carefully inspected under a binocular microscope and disintegrated into smaller pieces with dimensions <100 µm. To find the erionite/offretite crystals, several fragments were preliminarily checked by single-crystal X-ray diffraction, to extrapolate the unit-cell parameters. Finally, a crystal with dimension of approximately $0.05 \times 0.03 \times 0.015$ mm was identified as erionite.

A single crystal of erionite-Ag was glued on the tip of a glass fiber and mounted on a goniometer head. Diffraction data were collected on a Synergy-S Rigaku dual micro-focused source diffractometer equipped with a HyPix detector. The $\text{CuK}\alpha$ ($\lambda = 1.54184$) radiation was chosen for data collection due to the small dimensions of the crystal under investigation. An attempt to measure the same sample with $\text{AgK}\alpha$, available on the same machine, or with $\text{MoK}\alpha$ used for the Ag-levyne X-ray data collection, was not successful because of the low diffracting power of such a small crystal fragment. Diffraction data were integrated and corrected for absorption by using CrysAlis Pro (2018). Erionite crystal structure was solved by direct methods in space group $P6_3/mmc$.

Crystal data, collection, and refined parameters are reported in Supplemental¹ Table S1. The crystallographic information file¹ (CIF) of the refined structures has been deposited. The drawings of the crystal structures were produced by VESTA (Momma and Izumi 2011).

Molecular Dynamics (MD) simulations

Molecular Dynamics simulations were performed using the CP2K simulation package CP2K (2000–2019). The equations of motion were integrated using a 0.5 fs time step. The interatomic forces were calculated based on Density Functional Theory (DFT) using the Gaussian and plane waves methods (VandeVondele et al. 2005a). The electron exchange and correlations were described by Perdew–Burke–Ernzerhof functional (PBE) (Perdew et al. 1996). Dispersion interaction was taken into account using the DFT+D2 method (Grimme et al. 2006). The calculations were carried out in NPT ensemble (constant pressure and temperature using a fully flexible cell). Indeed, although atomistic simulations with fixed cell parameters can provide a satisfactory atomistic description of the extraframework content (Gatta et al. 2018), NPT ensemble was chosen in this study to take into account the strong disorder of the EF content and improve the convergence toward the stable configuration.

The simulations temperature of MD was set to 77 °C to prevent the glassy behavior of PBE- H_2O (VandeVondele et al. 2005b). The use of slightly elevated temperature makes sure ergodic dynamic of ions and water in the channels. The experimental measurements suggest that the space group symmetry does not change with in the given temperature range. The Kohn–Sham orbitals were expanded using a linear combination of atom centered Gaussian-type orbital functions. A “short-range” double-valence polarized basis set MOLOPT was used for each atomic kind (VandeVondele and Hutter 2007). Similar setup was successfully used in our previous simulations of zeolites (Cametti et al. 2019a, 2019b).

The simulation supercell ($2 \times 1 \times 1$) contained 684 atoms (36 Ag, 36 Al, 72 O, 216 O, 108 H_2O). The starting coordinates of the framework atoms were those of levyne-Ca (Cametti 2018). Silicon was randomly substituted by aluminum according to the bulk chemical composition following the Loewenstein’s rule (Loewenstein 1954). The Ag atoms were initially placed along the threefold axis parallel to $[001]$ in the middle of each $[4^6 6^8 3]$ cavity. The number of H_2O was set according to the idealized chemical composition of levyne that is 3.0 H_2O per EF cation (Passaglia and Sheppard 2001). The structural data were collected from a 25 ps long MD trajectory followed by at least 6 ps pre-equilibration. Moreover, two additional structural models with 2.5 and 2 H_2O per Ag atom, respectively, were tested.

RESULTS

The EDS-SEM analyses of the Ag-exchanged levyne showed that Na^+ was completely replaced by Ag^+ . The detected amount of potassium was related to the occurrence of erionite inter-

FIGURE 1. SEM BSD images of levyne-erionite intergrowths. (Color online.)

growths as confirmed by SEM pictures (Fig. 1). Within the same single crystal, two main domains can be recognized: one with a fibrous-like morphology, which mainly contains K and Ag as EF cations and, the other that is K-free. This kind of intergrowths, i.e., erionite on the {0001} faces of levyne lamellae is frequent and was observed in samples from different localities (Passaglia et al. 1974; Bennet and Grose 1978; Wise and Tschernich 1976; Gottardi and Galli 1985). Final chemical composition for Ag-levyne and -erionite are $\text{Ag}_{6.1}\text{Al}_{6.3}\text{Si}_{11.8}\text{O}_{36} \cdot 18.0\text{H}_2\text{O}$ and $\text{Ag}_{8.9}\text{K}_{1.7}\text{Al}_{10.1}\text{Si}_{22.5}\text{O}_{72} \cdot 30\text{H}_2\text{O}$, respectively.

Crystal structure of Ag-levyne

The Ag-levyne structure at room temperature preserves the space group $R\bar{3}m$ characteristic of the natural levyne-Ca. The aluminosilicate framework did not show significant changes because of Ag^+ uptake. The unit-cell parameters were comparable with those of the pristine material (Cametti 2018). The dimension ($6.48 \times 7.39 \text{ \AA}$) of the apertures of the eight-membered ring channels along [100] was similar to that of levyne-Ca ($6.44 \times 7.42 \text{ \AA}$).

The structural refinement of the XRD data indicated that Ag ions are strongly disordered within the zeolitic pores. Four main EF Ag sites (Ag1, Ag2, Ag3, and Ag4) were located plus additional low-occupied sites (Ag1A, Ag2A, Ag2B, Ag4A, ... Ag4E) (occupancy ~ 0.15) close to the main ones (Fig. 2; Supplemental Table S2). The Ag1 site is the most populated, with occupancy = 0.429(19). In Ag-levyne, the Ag sites (Ag1, Ag2, and Ag3) are distributed along the threefold axis and, different to the EF cations in natural levyne-Ca, at the wall of the eight-membered ring window of the *lev* cage (Ag4) (Fig. 2). Ag ions at this position are extremely disordered and a simultaneous presence of Ag and H_2O cannot be excluded.

In natural levyne-Ca (Cametti 2018), EF cations and H_2O are found at five sites: (C1, C2, C3, C4, C5) and (W1, W2, W3, W4, W5), respectively. In Ag-levyne:

- Ag1 site corresponds to C1 that in levyne-Ca is almost fully occupied by Ca;
- Ag3 site corresponds to C2, which in levyne-Ca is 13% occupied by Ca;
- Ag2, Ag2A, and Ag2B correspond to C3, C4, and C5, respectively; these positions in natural levyne-Ca, are partially occupied by Na, K, and Ca, respectively (Cametti 2018).
- The positions of Ag4 sites (Ag4A, Ag4B, Ag4C, Ag4D, and Ag4E) are comparable to those of H_2O at W2, W4, and W5 in levyne-Ca;
- W1 and W3 positions are identical in levyne-Ca and Ag-levyne.

Relevant bond distances of Ag-levyne structure are reported in Table 1. Ag1 site is coordinated by three H_2O at W1 [2.372(8) Å] and three framework-oxygen atoms at O2 [2.470(5) Å], forming a fairly regular octahedron. Ag2 site bonds to six framework-oxygen atoms at O5 [2.591(5) Å], which constitute the aperture of the six-membered ring window of the *lev* cavity. Bond distances between 2.24 and 2.6 Å are found for Ag4A, Ag4B, Ag4C, Ag4D, and Ag4E. On average, the sites at these positions bond to three oxygen atoms of the eight-membered ring aperture (two at O1 and one at O3) and two H_2O at W3.

The total number of Ag ions per formula unit obtained by the structural refinement was lower compared to that estimated by the chemical analyses. On the basis of 36 oxygen, the total number of positive charges required to balance the negative charge of the aluminosilicate framework is 6. However, if all the EF sites are refined with the Ag scattering factor, the refined Ag^+ apfu

FIGURE 2. Crystal structure of Ag-levyne projected along [110]. Blue spheres represent the (Si, Al) tetrahedral sites, silver and oxygen atoms are displayed in gray and red, respectively. Partially colored spheres correspond to partial occupancy of the crystallographic sites. The yellow line indicates the threefold axis. (Color online.)

is only 4, pointing out that ~30% of the EF silver could not be located by XRD.

Molecular Dynamics

The unit lattice constants obtained by MD simulations are close to those obtained by XRD, with a deviation of <1% for all parameters and 1.75% for the length of the c-axis (Table 2).

Figure 3 reports a snapshot of the structure obtained after 20 ps calculation. Ag atoms are found mainly along the threefold axis and part of them are displaced toward the eight-membered ring window of the *lev* cavity. The radial distribution function (RDF) and running coordination number (CN) of the Ag-O (O oxygen of the framework) and Ag-Ow (Ow oxygen of the H₂O)

FIGURE 3. A snapshot of Ag-levyne structure after 18 ps MD simulation. Color code as in Figure 2. Al-occupied tetrahedral sites are shown as dark cyan spheres. Ag-O bonds are shown with gray lines. (Color online.)

are reported in Figure 4. The RDF of the Ag-Ow distances shows a clear peak at 2.43 Å, whereas the curve corresponding to Ag-O indicates a broadened distribution of distances with a maximum at ca. 2.5 Å. On average, each Ag is surrounded by ~2 H₂O and 1 framework oxygen at distances between 2.43 and 2.60 Å.

The Ag ions in the *lev* cavity are found at the top and bottom of the cavity, close to the aperture of the six-membered rings (Fig. 5a). These atoms are coordinated by three-framework O atoms and by three H₂O, which occupy the central part of the cage. Additional Ag ions, located at the eight-membered ring windows, bond to two framework oxygen atoms and to two or three H₂O (Fig. 5a). Such Ag distribution in the *lev* cavity agrees with that observed by the structural refinement (Fig. 5b) where Ag ions disordered at Ag4 sites are located on the wall of the aperture of the eight-membered ring. Additional disordered Ag atoms at Ag2 sites are distributed at the bottom of the cage.

In the simulation's setup with 3 H₂O per Ag atom, an additional Ag ion is found at (0,0,0), in the middle of ~83% of

FIGURE 4. Radial distribution function (RDF) (continuous line) and coordination number (CN) (dotted lines) of Ag-O and Ag-Ow distances of Ag-levyne calculated from MD trajectories. (Color online.)

the double six-membered rings (D6R) cage (Fig. 3). In contrast, in the structural refinement, no residual electron density was found at this position and an attempt to insert an additional site at (0,0,0) was not successful.

The hydrogen bond net of the structure with 3 H₂O mainly involves oxygen of the water molecules, whereas no significant interactions between H and framework O atoms were observed (each O has approximately only 0.2 H atoms within 2.0 Å, Supplemental Material¹ Fig. S1). The RDF and CN of Ow...H contacts show that, on average, 0.5 H are found at a distance of 1.70 Å from Ow, indicating a medium-strong character of such interactions (Supplemental Material¹ Fig. S1). As expected, the number of the Ow...H contacts decreases and becomes less significant if the modeled structures with 2 and 2.5 H₂O per Ag ion are considered (Supplemental Material¹ Fig. S2). Detailed analysis of the Ow-H RDF shows that in agreement with expected more acidic properties of the H₂O coordinating the Ag-ion, proton donation events take place between water in Ag-coordination shell and interstitial water (Albuquerque and Calzaferri 2007; Fois and Tabacchi 2019).

Crystal structure of intergrown Ag-erionite

erionite (Alberti et al. 1997) is preserved after the uptake of Ag ions. The unit cell [$a = 13.29919(19)$, $c = 15.19312(19)$ Å, $V = 2327.17(7)$ Å³] is slightly smaller compare to that of an erionite sample from the same locality [$a = 13.345(1)$, $c = 15.124(3)$ Å, $V = 2332.6(5)$ Å³] reported by Passaglia et al. (1998). According to the structural refinement, K occupies the middle of the cancrinite cage, where it is slightly displaced along z direction as demonstrated by the occurrence of an additional site K1A [occupancy = 0.030(16)] at 0.8(3) Å from K1 [occupancy = 0.98(4)] (Fig. 6). This finding is in agreement with Sherry (1979) who reported that potassium in the cancrinite cavities cannot be replaced via ion exchange in aqueous solution because of the small opening of the six-membered ring window, which hampers the passage of the K ions.

Ag ions are distributed in the *eri* cavity, at disordered sites with partial occupancies (Fig. 6). Three main positions can be recognized:

- C1, the most occupied site [occupancy = 0.679(14)] is located in the erionite cavity close to the six-membered

FIGURE 6. Crystal structure of Ag-erionite refined from XRD. Color code as in Figure 2. Purple spheres represent K atoms. Gray lines indicate Ag-O bonds in the *eri* cavity. (Color online.)

ring aperture of the cancrinite cage; it forms two bonds with framework oxygen at O6 [2.500(6) Å] and two longer connections [2.986(5) Å] with those at O4. A very low occupied site C1A close to C1 indicates, also in this case, a displacement from the mirror plane perpendicular to [001].

- C2, disordered at three different subsites (C2, C2A, C2B, with total occupancy = 0.53) distributes at the bottom and top of the erionite cavity in the aperture center of the 6-membered rings. Ag ions at this position form bonds with framework oxygen O5 of the six-membered ring and with H₂O at W5 site, which is located along the threefold axis.
- C3, C3A, and C3B (total occupancy = 0.21) are located in the middle of the *eri* cavity and bond only to H₂O at W5A and W4A.

All water molecules, but those at W5 and W5A, are distributed over five sites at the wall of the *eri* cavity in correspondence of the 8-membered ring window (Supplemental¹ Table S3; Fig. 6).

The total number of positive charges obtained by the structural refinement (11.3⁺) is in reasonable agreement with that estimated by the chemical analysis (12.3⁺).

DISCUSSION

The analysis of the erionite intergrowths demonstrated that all EF cations in the *eri* cavity could be exchanged with Ag⁺, and, differently from Ag-levyne, all Ag ions in the unit cell could be located by the structural refinement. The lack of ca. 30% of Ag⁺ in Ag-levyne structure can be explained by (1) migration of part of silver toward the external surface, or (2) strong disorder of the remaining Ag⁺ in the structural voids, which prevents its exact location.

Since positional disorder of EF sites was observed also in Ag-erionite, but all Ag could be located, we decided to collect additional XRD data on Ag-levyne by using the more brilliant Cu micro-focused source employed to investigate Ag-erionite. The other two fragments of Ag-levyne were selected and data were collected on the same instrument used for Ag-erionite. As an example, data-collection parameters and results obtained for the first fragment are reported in Supplemental¹ Tables S4 and S5. Structural refinements did not show any significant change in terms of EF cation positions, but, in both cases, the refined chemical composition indicated an Ag content higher than 5 apfu. Such a value can be reasonably accepted if the errors on refined values of both occupancies and thermal parameters are taken into account (Supplemental¹ Table S5). Thus, the disorder hypothesis 2 seems the most reasonable. Such a hypothesis is also supported by similar findings in hydrated fully exchange Ag-chabazite and Ag-heulandite (Nevenka et al. 1981; Calligaris et al. 1983). In both cases, the authors could not locate by XRD methods all Ag ions revealed by the chemical analyses. In Ag-exchanged heulandite, only 56% of exchanged Ag⁺ was detected by X-ray (Nevenka et al. 1981). Similarly, in Ag-chabazite only 61% Ag⁺ could be placed by the structural refinement (Calligaris et al. 1983). The interpretation given by the authors was that remaining Ag ions “spread out in the channels of the zeolite... giving no detectable contribution to the diffraction pattern” (Nevenka et al. 1981).

According to our findings, the distribution of Ag⁺ in the two intergrown phases slightly differs. In erionite, the disorder that affects the Ag ions is less pronounced; with the exceptions of C1A, C3A, and C3B sites, the occupancies of all EF sites are higher than 0.15, and most of the Ag is found at C1 site [occupancy = 0.679(14)]. In Ag-levyne, apart from Ag1 [occupancy = 0.429(19)], ions are distributed at sites with occupancies <0.15. In particular, silver ions at the wall of the *lev* cavity are significantly disordered and affected by high displacement parameters that strongly influence the final values of the refined occupancies.

Overall, the exchange of the original EF cations with Ag⁺ in the levyne structure does not induce significant structural modifications of the framework. The Ag⁺ ions distribute at different crystallographic sites compared to levyne-Ca and to levyne-Na. In particular, the sites at Ag4-Ag4E sites are located at the aperture of the eight-membered rings of the *lev* cavity where natural levyne H₂O molecules are found. Such distribution was confirmed by the MD simulations, which indicated a displacement of the EF cations away from the threefold axis. MD trajectories also pointed out the occurrence of a silver ion located inside the D6R cage. However, according to XRD results, no residual electron density was found at this position.

To explain this mismatch, we have to keep in mind that in real exchange experiments, not only the availability but also the accessibility of the EF sites must be considered; the latter is related to the kinetic behavior of the ion-exchange system and thus to the diffusion coefficients of that specific ion within the pores (Inglezakis et al. 2004). The diffusion and the ability of an ion to access a specific site may depend on its hydration shell. From the structural refinement, we could not unambiguously determine the exact water content, due to the strong disorder of the EF occupants. MD simulations with 3 H₂O per Ag ion, represent an idealized chemical composition of levyne-(Ca_{0.5}Na)₆ (Passaglia and Sheppard 2001). However, in Ag-levyne, the number of EF cations is 1.5 greater than in levyne-Ca (1 Na plus 2.5 Ca apfu). A possible reason for the presence of Ag⁺ inside the D6R cage could be the overestimation of the number of structural H₂O; less room for Ag ions in the *lev* cavity would force them to enter inside the D6R cage. To test the effect of H₂O amount on the Ag distribution in LEV framework type, additional Molecular Dynamics simulations (12 ps long trajectories) of Ag-levyne structure with different water content were performed. At first, we hypothesized 2.5 H₂O (instead of 3) per Ag ion, which is 15 H₂O pfu. With such configuration, only 30% of the D6R cage is occupied by an Ag ion. When removing an additional 0.5 H₂O, i.e., modeling a structure with only 2 H₂O per Ag ion (12 H₂O pfu), no EF cations are found inside the cage at (0,0,0) (Fig. 7). In both cases, displacement of part of Ag ions from the threefold axis toward the 8-membered ring window was observed.

Based on these results, the structure containing 2 H₂O per Ag ion represents the best agreement between experimental (XRD) and calculated (MD) Ag-levyne. It should be kept in mind that the amount of structural (and absorbed) water in a zeolitic material is strongly influenced by the environmental conditions the sample is exposed to (i.e., relative humidity, temperature). It is worth mentioning that in one of the data sets collected as a test (by using the Cu micro-focus source) on a fragment of Ag-levyne,

FIGURE 7. Perspective view of the simulated (11 ps) Ag-levyne supercell with 2 H₂O per Ag ions. Color code as in Figure 3. Ag ions are not found in the D6R cages. (Color online.)

a tiny peak at (0,0,0) appeared in the difference Fourier maps. Nevertheless, an attempt to insert it in the structural refinement did not lead to satisfactory results; the refined value was as big as the computed error. Interestingly, the occurrence of a cation at this position, i.e., (0,0,0), was found in the dehydrated form of levyne-Ca (Arletti et al. 2013; Cametti 2018).

IMPLICATIONS

Currently, natural zeolites are effectively applied for wastewater treatment and removal of contaminants. On the other hand, their use in other important fields such as catalysis or gas separation processes is still limited. In the last decades, much effort has been made to improve the catalytic and separation potential. The functionalization and modification of the natural zeolites by thermal treatment or ion-exchange has been one of the most used and successful technique (Zukal et al. 2010; Ma et al. 2018; Abreu et al. 2019; Velazquez-Peña et al. 2019). The specific case of Ag-modified zeolites is particularly interesting because silver is known to strongly influence the adsorption characteristics of aluminosilicate zeolites (Hutson et al. 2000). For example, modified Ag-ferrierite and Ag-mordenite are applied in air purification processes (Ar/O₂ enrichment or exhaust gas cleanup) (Knaebel and Kandybin 1993; Ogawa et al. 2001). In addition, Ag-exchanged zeolites have attracted great attention due to their remarkable luminescent and photocatalytic properties (De Cremer et al. 2009; Countino-Gonzales et al. 2015; Aghakhani et al. 2018). In this context, particular attention must be paid not only to the framework topology and to the size of the micropores but also, and especially, to the cation positions in the structural voids (Seifert et al. 2000; Aghakhani et al. 2018; Fron et al. 2019). Previous research on transition-metal modified zeolites have shown that even if the structure experiences little modifications of the framework at room temperature, the new extraframework cations have a significant influence on

the dehydration path (i.e., phase transformations) and thermal stability of the newly produced zeolite. With this respect, a high-temperature structural study is in progress to check whether Ag-levyne will undergo, upon heating, different structural changes compare to levyne-Ca.

ACKNOWLEDGMENTS

We are thankful to B. Hoffman of Natural History Museum of Bern who provided the levyne sample, M. Nagashima for her help with EMPA analyses, and to T. Armbruster for reading the manuscript. Gloria Tabacchi and an anonymous reviewer are thanked for their very constructive comments.

FUNDING

We acknowledge access to the Swiss National Supercomputing Center (CSCS) and UBELIX HPC cluster at the University of Bern. The Swiss National Science Foundation (SNF) is acknowledged for the Ambizione grant no. PZ00P2 173997 awarded to G.C. and for the R'Equip grant n. 206021_177033 awarded to P. Macchi.
