Abstract. Log wood burning is a significant source of volatile organic compounds including aromatic hydrocarbons (ArHC). ArHC are harmful, reactive in the ambient atmosphere, and important secondary organic aerosol (SOA) precursors. Consequently, SOA is a major fraction of the total organic aerosol emitted by log wood burning. ArHC reduction is thus critical in the mitigation of adverse health and environmental impacts of log wood burning. In this study, two Pt-based catalytic converters were prepared and tested for the mitigation of real-world log wood burning emissions, including ArHC and SOA (studied using a potential aerosol mass oxidation flow reactor), as well as toxic carbon monoxide (CO) and methane, a greenhouse gas. Substantial removal of mono- and polycyclic ArHC and in particular phenolic compounds was achieved with both catalysts operated at realistic chimney temperatures (50% conversion was achieved at 200 and 300°C for non-methane hydrocarbons in our experiments for Pt/Al₂O₃ and Pt/CeO₂-Al₂O₃ respectively). The catalytically cleaned emissions exhibited a substantially reduced SOA formation already at temperatures as low as 185 to 310°C, which substantially lowers the total PM burden of log wood burning. Thus, catalytic converters can effectively reduce primary and secondary log wood burning pollutants and thereby, their adverse health and environmental effects.

Introduction

Residential wood burning (WB) is often reputed to be a climate-neutral heating method due to its renewable nature and the emission of biogenic CO₂, formed from carbon recently accumulated by plants. However, residential WB performed under non-ideal conditions is a known and substantial source of primary particulate matter (PM), toxic carbon monoxide (CO) and harmful volatile organic compounds (VOC) impacting air quality and human health.¹⁻⁵

Primary PM in the submicron particle size range includes refractory material, such as

elemental or black carbon (EC, BC) but may be dominated by non-refractory material such as primary organic aerosol (POA). For instance, ref.⁶ reported POA/BC ratios of 2-14 for log wood burning. In addition to primary PM emissions, formation of particulate secondary organic aerosol (SOA) from the atmospheric transformation of emitted reactive precursors is significant, reaching SOA/POA ratios of at least 3-7 in laboratory studies.^{4, 6-9}

Harmful VOC emissions include aromatic, oxygenated aromatic and polycyclic aromatic hydrocarbons (ArHC).⁵ They are not only known to cause serious health issues in humans, through their carcinogenic effects (e.g. benzene is known to

cause leukemia) or by deteriorating developmental, nervous, and heart and blood vessel systems¹⁰⁻¹², but have also been identified as important SOA precursors in combustion emissions.^{5, 9, 13-15} Their relevance for ambient SOA formation is related to their reactivity towards hydroxyl radicals, and the formation of low-volatility compounds upon only few radical attacks,^{16, 17} which allows rapid condensation to the particle phase under typical atmospheric conditions. Additionally, incomplete WB leads to methane (CH₄) emissions¹⁸⁻²⁰, which contribute relatively less to SOA formation owing to low SOA yields.²¹ However, methane emissions impact the environment by their high global warming potential.

Primary WB emissions (PM, CO and VOC including CH₄) can be reduced by educational outreach, given the relevant influence of operator behavior²²⁻²⁴, as well as by automating operation³ or improving burner technology.^{6, 8, 25} Switching from conventional log wood stoves to potentially cleaner automated systems or wood chip and pellet operation can be costly, might require incentives, and depends strongly on feedstock availability. While such measures will significantly reduce the emissions²⁶, they need to be combined with secondary pollutant abatement strategies in order to reduce the toxic and harmful pollutants to close-to-zero levels for all appliance types in the future. Mechanical measures such as electrostatic precipitators may reduce primary PM, but catalytic conversion is required for efficient CO and VOC removal²⁷, and the associated abatement of SOA. The use of catalytic converters has been explored at lab and pilot scale, focusing on the major primary pollutants including gases and primary particles²⁷⁻³⁷, but studies lack any assessment of SOA abatement. As also the application of catalytic converters remains challenging^{31, 37}, further scientific studies are needed to establish their potential, especially when considering trace pollutants.

Here, we demonstrate simultaneous and significant reduction of harmful CO, aromatic hydrocarbons, and SOA (through the removal of its precursors) from log wood stove emissions using Pt-based honeycomb catalytic converters.

Material and Methods

Wood burning (WB) experiments. Our appliance^{4, 5, 9} was fueled with dry beech wood (*Fagus sylvatica*). The emissions were sampled from the chimney over the whole burning cycle using a heated ejector diluter (150°C) and injected into a custom-built 3 m³ Teflon chamber, made of 125µm thick collapsible DuPont Teflon fluorocarbon film (FEP) type 500A, Foiltec GmbH, Germany. Dilution air was provided by a pure air generator system, which we described previously.^{13, 38} The obtained well-mixed feed was diluted further with humidified clean air in the Teflon chamber and then passed alternately through a quartz glass reactor³⁹ containing a catalytic monolith at a flow rate of 5±1 L min⁻¹ (gas hour space velocity, GHSV=135 L g⁻¹ h⁻¹) and a by-pass line (80°C) as shown in Figure S1. Behind the quartz glass reactor or by-pass line, the feed was diluted with clean dry air to provide suitable concentrations for the downstream analytical instruments, listed in Table S1, and fed to an oxidation flow reactor during photochemistry experiments (described below). The monolith was actively heated, and progressively set from 600 to 100°C. Each temperature set-point was held for at least 5 min once the temperature stabilized. The quartz glass reactor was equipped with two 1 mm thermocouples positioned up- and downstream the monolithic catalyst. Compared to lab scale experiments³⁹, ceramic beads were not used upstream of the monolith in order to avoid particle losses, which caused, however, a large discrepancy between the temperature measurements up- and downstream and the actual set-point of the monolith (Figure S2). Therefore, we provide the set-point temperature. The catalysts were exposed to WB emissions containing CO₂ (3400-10500 ppm), CO (360-1100 ppm), CH₄ (65-220 ppm), non-methane hydrocarbons (NMHC, 80-260 ppmC) including aromatic hydrocarbons (ArHC, 70-320 ppmC), 1-3 vol% H₂O and refractory as well as non-refractory primary aerosol particles. The modified combustion efficiency (MCE) determined as the ratio of CO₂ to (CO+CO₂) was 0.89-0.93 across all experiments. Feed concentrations are reported in Table 1 and Table 2, and refer to averages±1SD of the concentrations determined from by-pass measurements conducted

at start, end and intermediate to selected temperature set-points. Catalytic conversion rates and pollutant reductions were calculated by comparison of catalytically cleaned emissions to by-pass measurements of the corresponding experiment. Feed concentrations were subject to burn-to-burn variability as well as deliberate adjustments of the dilution factor in the Teflon chamber. Each experiment was conducted with emissions from a separate burn and Teflon chamber filling, experiment nomenclature is detailed below. Typically we conducted one experiment per day. The Teflon chamber was cleaned at the end of each experiment by injection of humidified air, ozone (O_3 , 1 ppm) and exposure to UV lights for 1 hour. Thereafter, it was flushed with dry clean air over night and refilled to about one third of its volume with humidified clean air before the next experiment.

Catalyst preparation. The catalyst powders ($\text{Pt}/\text{Al}_2\text{O}_3$ and $\text{Pt}/\text{CeO}_2\text{-Al}_2\text{O}_3$) were obtained by wet impregnation of chloroplatinic acid (H_2PtCl_6 , Fluka) on $\gamma\text{-Al}_2\text{O}_3$ (200 μm ; Puralox SCCa150/200, Sasol) and $\text{CeO}_2\text{-Al}_2\text{O}_3$ (30 wt% CeO_2), which was prepared by deposition-precipitation ($\text{Ce}(\text{NO}_3)_3 \cdot 6\text{H}_2\text{O}$ on the same $\gamma\text{-Al}_2\text{O}_3$). The final Pt content was ca. 1.3 wt% as determined by elemental analysis. After drying overnight at 90°C , the powders were calcined in static air at 500°C for 2 h. Cordierite monoliths (cell density=600 cells per square inch; length=77 mm, diameter=20 mm, Figure S3) were dip coated in an aqueous slurry of the catalyst powder and a colloidal Al_2O_3 binder (Disperal, Sasol), calcined at 600°C for 6 h, and then aged in 10 vol% $\text{H}_2\text{O}/\text{N}_2$ at 600°C for 10 h in a tubular quartz reactor. Monoliths were placed in a quartz glass reactor³⁹ for the experiments as described above.

Catalyst stability. We determined methane (CH_4) conversion rates on the catalytic monoliths using synthetic reactor feeds in the lab before and after exposure to WB emissions (section S2.1 provides the conditions). As shown in Figure S3, exposure to WB emissions left deposits indicated by a change in monolith surface color. Regardless of deposits, we did not observe any adverse effect on the CH_4 conversion. While this indicates good stability, further assessment in long-term exposure experiments is suggested.

Photochemistry experiments. Secondary organic aerosol (SOA) formation was simulated using a potential aerosol mass oxidation flow reactor (OFR),^{15, 38} which has been successfully applied to WB emissions earlier.^{25, 38, 40} The OFR consisted of a 0.015 m^3 cylindrical glass chamber. It contained two low-pressure mercury UV lamps, each with discrete emission lines at 185 and 254 nm, for hydroxyl radical generation from in-situ generated O_3 (8 ppm) and H_2O (15-20% relative humidity), which was provided via a Nafion humidifier. Butanol-D9 was injected separately into the OFR and used to determine the hydroxyl radical concentration.⁴¹ The plug flow residence time was 100 s. SOA was determined as the organic particulate mass increase when OFR UV lamps were switched on. SOA of fresh emissions (i.e. emissions fed into the OFR through the by-pass line) was compared to that of catalytically cleaned emissions using $\text{Pt}/\text{Al}_2\text{O}_3$ at 185°C , and $\text{Pt}/\text{CeO}_2\text{-Al}_2\text{O}_3$ at 185, 200, 250 and 310°C . OFR experiments were conducted at a median hydroxyl radical concentration of 1.1×10^9 molecules cm^{-3} (fresh emissions) and 1.5×10^9 molecules cm^{-3} (catalytically cleaned emissions). This corresponds to a median atmospheric reaction time of 29 hours (fresh) and 38 hours (catalytically cleaned, Table S2), assuming a mean ambient hydroxyl radical concentration of 1×10^6 molecules cm^{-3} following ref.⁴². Recent publications presented in depth characterization operating conditions of OFRs⁴³⁻⁴⁶ and loss estimates of low-volatility compounds within the system.⁴⁷ However, the here presented experiments were conducted before these assessments were available. Operating conditions were instead in line with previous experiments^{15, 38} that yielded good agreement with smog chambers (considered to provide representative atmospheric processing in the past). The newer literature⁴³⁻⁴⁷ suggests that the here presented OFR experiments were conducted at an external hydroxyl radical reactivity ($\text{OHR}_{\text{external}}$) of $400\text{-}1350\text{ s}^{-1}$ for fresh emissions. Experiments with catalytically cleaned emissions were more diluted ($\text{OHR}_{\text{external}}$: 2 s^{-1} at 310°C , 230 s^{-1} at 250°C and 300 s^{-1} at 185°C). Model results for photolysis by UV and a discussion of the influence of nitrogen oxides are presented in SI section S3.

Instrumentation and data processing. Methane (CH_4), CO and CO_2 were measured using a cavity ring-down spectrometer (CRDS, Picarro). NMHC was calculated as the difference from flame ionization detection (FID, Horiba) of total hydrocarbons (THC) and CH_4 . We observed interference in the measurement at high ratios of CH_4 /NMHC. Therefore, at high catalytic conversion of NMHCs (>0.5) and in the presence of the yet initial CH_4 concentration, the CRDS-determined CH_4 signal was used to calculate the NMHC. VOCs were characterized by a proton transfer reaction time-of-flight mass spectrometer^{48, 49} (PTR-ToF-MS; PTR-TOF-8000, Ionicon) using hydronium ions as the primary reagent. PTR-TOF-8000 settings, data processing, ion identification and quantification were as described earlier.^{5, 9} Relevant ions and concentration levels are given in Table 2. The organic particulate matter (PM) was characterized using an aerosol mass spectrometer (HR-ToF-AMS, Aerodyne) equipped with a PM_1 aerodynamic inlet lens.⁵⁰ HR-ToF-AMS calibrations and data processing were as described earlier.^{9, 51} A relative ionization efficiency of 1.4 (ref. ⁵¹) and an experimentally determined collection efficiency (0.6 ± 0.1 , Table S2/Figure S11) were applied to organic PM. Data were

corrected for gas-phase CO_2 by measurements of particle-free emissions. Contribution of nitrate salts was negligible and no further CO_2^+ correction was required.⁵²

Experiment Nomenclature. We conducted experimental sets as described in the following:

- E3-E10 denote WB experiments throughout the manuscript. E5 ($\text{Pt}/\text{Al}_2\text{O}_3$) and E3, E7, E8, E9 ($\text{Pt}/\text{CeO}_2\text{-Al}_2\text{O}_3$) refer to catalytic cleaning of primary WB emissions.
- E6 ($\text{Pt}/\text{Al}_2\text{O}_3$), and E4, E10 ($\text{Pt}/\text{CeO}_2\text{-Al}_2\text{O}_3$) denote photochemistry (SOA) experiments. These were conducted as add-on to E5, and E3, E9 respectively. For E6, and E4, E10 a higher dilution ratio was deployed in the Teflon chamber in order to reduce concentration levels for the subsequent OFR experiments. Catalytic conversion of primary WB emissions was therefore re-determined. We present the CO conversion for comparison in Figure S6.
- Catalyst stability was monitored by determining CH_4 conversion using synthetic reactor feeds in the lab before (E1, E2) and after (E11, E12) exposure to WB emissions. Details are provided in SI section S2.1.

Table 1. Gas phase concentrations in the WB emissions feed (average concentration in Teflon chamber).

*Measurements based on cavity ring-down spectrometry (CRDS, Picarro). **Measurements based on flame ionization detection (FID) for THC and CH_4 , with the difference yielding the NMHC. NMHC values in brackets give the calculated NMHC as the difference between FID THC and CRDS CH_4 . ***E6 and E4, E10 are OFR (i.e. photochemistry/SOA) experiments during which the fresh primary WB emissions were also catalytically cleaned; E5 and E3, E7, E8, E9 are fresh emissions experiments w/o subsequent SOA formation. Note that all concentration levels here refer to the feed for the catalytic converters; emissions were diluted at least 8-fold before being fed to instrumentation/OFR.

Results and Discussion

Primary gaseous emissions. Catalytic conversion of CO, non-methane hydrocarbons (NMHC), specific volatile organic compounds (VOC) and

methane was determined in wood burning (WB) emissions. Both tested catalysts were effective for the abatement of these species. They displayed distinctly different behavior in their temperature-dependent conversion curves.

Figure 1. Catalytic conversion of a) CO, b) NMHC and c) methane (CH₄) on Pt/Al₂O₃ and Pt/CeO₂-Al₂O₃ in wood burning (WB) emissions. E5 and E3, E7, E8, E9 denote different experiments using fresh emissions (Table 1).

Significant removal of CO and NMHC was achieved at temperatures representative of startup and operation of wood appliances.²⁸ The temperature of 50% conversion (T_{50}) was significantly different between the two catalysts, but equal for CO and NMHC for a given catalyst. Pt/Al₂O₃ provided better conversion at lower temperature (T_{50} , 200°C) than Pt/CeO₂-Al₂O₃ (T_{50} , 300°C). Both systems yielded a conversion $\geq 95\%$ at 400°C (Figure 1). Methane (CH₄) is characterized by a relatively low reactivity in the atmosphere and generally in chemical reactions, which makes its catalytic abatement more challenging.⁵³ While palladium is considered generally more efficient, platinum-based catalysts offer more resistance to sulfur. In our experiments, methane required higher reaction temperatures than CO and NMHC, yet, both catalysts reached significant conversion at 600°C. In contrast to our observations for CO and NMHC, Pt/CeO₂-Al₂O₃ exhibited a significantly enhanced methane conversion between 400 and 600°C compared to Pt/Al₂O₃. CeO₂ clearly facilitated methane oxidation, which is often attributed to the improved redox properties of the catalyst.^{54, 55}

The NMHC emissions were dominated by benzene (44-234 ppmC) and contained also naphthalene (8-40 ppmC) and phenolic compounds (8.6-23 ppmC) along with styrene (1.4-4.6 ppmC) and oxygenated aromatic or unsaturated oxygenated compounds, e.g., benzaldehyde (1.0-4.1 ppmC) and furans (1.2-3.6 ppmC). Overall, the composition (Table 2/Figure 3a) was in line with our previous findings.^{5, 9} Concentration levels represented real-world stove operation, albeit our

emissions correspond to relatively poor combustion conditions (indicated by the modified combustion efficiency, MCE, of 0.89-0.93). Both catalysts significantly removed aromatic hydrocarbons (ArHC) from WB emissions (Figure 2).

Functionalized molecules, such as phenolic ArHC (phenol, methylphenol, dimethylphenol), and also ArHC with carbonyl functions (e.g. benzaldehyde) were removed in significant amounts already at lower temperatures than their non-functionalized analogues (monocyclic and polycyclic ArHC). The abatement was nearly complete at set-point temperatures as low as 185°C for phenolic compounds. We could not assess decisively whether the losses on the ceramic monolith and on the Al₂O₃, which can act as cold-traps, contributed to the removal of phenolic compounds below 185°C (Figure S5). Nevertheless, the removal either by the temporary storage on cold-surfaces (and catalytic conversion once temperatures are sufficiently high) or by the direct catalytic abatement at low temperature is beneficial to reduce the health impact of the emissions, and had substantial effects on the reduction of the SOA potential (see below).

Various non-oxygenated ArHC of increasing molecular weight such as benzene, toluene, styrene and naphthalene exhibited temperature dependent conversion. While Pt/Al₂O₃ converted these components and CO simultaneously, Pt/CeO₂-Al₂O₃ discriminated between different ArHC (Figure 2). It exhibited considerably higher activity for the conversion of more reactive compounds. This is reflected in the varied T_{50} in the series. Benzene was oxidized in

the same temperature regime as CO. Molecules with higher reactivity such as polycyclic ArHCs (e.g., naphthalene), or unsaturated functionalities (e.g., styrene) converted at lower temperatures than more stable, less reactive molecules (e.g., toluene and benzene; in line with their atmospheric reaction rate constant towards hydroxyl radicals (k_{OH}), see Table 2 and Figure 2). Typically, higher temperatures (+20 to +100°C depending on the molecule) were needed with Pt/CeO₂-Al₂O₃. Nevertheless, ArHCs were completely removed from the emissions by both catalysts at representative exhaust gas temperatures of 220°C (Pt/Al₂O₃) and 350°C (Pt/CeO₂-Al₂O₃) demonstrating feasibility of the catalytic abatement.

SOA precursor identification and quantification ("SOA-22 precursors"). The species listed in Table 2 were identified as important precursors for SOA formation in wood burning emissions by an earlier study.⁹ Here we refer to the collection of these species as the sum parameter "SOA-22 precursors". The relative contribution of each species to the total available gas-phase mass as determined by PTR-ToF-MS is presented in Figure

3a. The sum of SOA-22 precursors accounted for $97 \pm 0.5\%$ (based on mass in $\mu\text{g m}^{-3}$) of all potential SOA precursors identified in our fresh emissions. Henceforth, SOA-22 are used as a surrogate for all SOA precursors in our study. The largest fraction to the SOA-22 gas-phase mass was contributed by benzene (58-72%), naphthalene (11-12%), and phenol (6-9%), as displayed in Figure 3a.

In order to estimate the fraction of relevant SOA forming carbon mass to the total available gaseous organic compounds the SOA-22 precursor fraction was compared to the total PTR-ToF-MS derived organic and carbon mass, as well as the FID-based carbon mass. The SOA-22 precursors accounted for $49 \pm 9\%$ of the total PTR-ToF-MS detectable organic gas-phase mass ($\mu\text{g m}^{-3}$), which corresponded to $65 \pm 8\%$ if considering the carbon fraction ($\mu\text{gC m}^{-3}$). The remainder (51% and 35% respectively) was dominated by small oxygenated organic species, such as e.g. methanol and acetic acid, as also observed in earlier experiments.^{5, 9} These compounds do not significantly contribute to SOA formation during atmospheric oxidation owing to their small carbon backbone.

Figure 2. Catalytic conversion of specific aromatic hydrocarbons. a) Pt/Al₂O₃ (E5), **b)** Pt/CeO₂-Al₂O₃ (average ± 1 standard deviation of E3, E7, E8 and E9). Losses of compounds are discussed in Figure S5. CO and NMHC are displayed for comparison. Numbers in brackets in the legend indicate atmospheric hydroxyl radical rate constants ($10^{-12} \text{ cm}^3 \text{ molecules}^{-1} \text{ s}^{-1}$, Table 2).

E3-E10 denote different experiments (Table 1). *E6 and *E4, *E10 are OFR experiments; the relative composition within those corresponds to E5 and E3, E9 conducted within the same experimental set. Compound classes: mono-c.=monocyclic ArHC), PAH=polycyclic ArHC, phOH=phenolic ArHC, non-ArHC=aliphatic compounds, furan=furans, ox. ArHC=oxygenated ArHC other than phenolic compounds. °NMOC=non-methane organic compounds. Note that concentration levels refer to the feed for the catalytic converters; emissions were diluted at least 8-fold before fed to instrumentation/OFR, see set-up in Figure S1. ^{a)} Ions are referred to with their integer mass-to-charge ratio (*m/z*) for simplicity, but are identified based on the exact *m/z*. ^{b)} proton transfer reaction rate constant^{5,9}, $k_{\text{H}_3\text{O}^+}$, 10⁻⁹ cm³ s⁻¹. ^{c)} atmospheric hydroxyl radical rate constants⁵⁶⁻⁶⁴, k_{OH} , 10⁻¹² cm³ molecules⁻¹ s⁻¹ (range in brackets corresponds to isomers and spread in reported data). ^{d)} SOA yield, Y_{SOA} , (μg SOA per μg reacted SOA precursor) applied here based on ref.⁹.

In order to obtain further information about our mass closure and the validity of using the FID-based NMHC signal as a predictor for SOA-22

precursors, we compared the PTR-ToF-MS measurements to the FID-based NMHC signal. The ratio of PTR-ToF-MS-to-FID was 1.6±0.3

ppmC:ppmC considering the complete PTR-ToF-MS carbon mass. Both instruments are selective towards specific compound classes, and an obtained ratio may thus be close to 1 due to compensating errors. While oxygenated compounds with short carbon (as were observed by the PTR-ToF-MS, e.g. methanol) have limited response on the FID, aliphatic compounds are detected only selectively⁷ by PTR-ToF-MS. This is elaborated further in the SI (section S3).

SOA formation. SOA formation was studied experimentally via exposure of the emissions to hydroxyl radicals in an OFR. We assessed the contributions of the individual SOA-22 species to the OFR reacted gaseous precursor mass (Figure 3b), and predicted a corresponding SOA-22 particle phase mass (Figure 3c).

The largest contributors to the OFR reacted SOA-22 precursor mass were phenol (22-28%), naphthalene (21-29%) and benzene (6-29%). This results from species' abundance becoming essentially weighted by their corresponding atmospheric reactivity upon OFR photochemistry (k_{OH} , in units of $10^{-12} \text{ cm}^3 \text{ molecules}^{-1} \text{ s}^{-1}$, Table 2). Among these three species, k_{OH} is highest for phenol (28), followed by naphthalene (23), and lowest for benzene (1.22). Therefore, contributions of phenol and naphthalene increased relative to benzene in Figure 3b.

In order to predict the SOA-22 particle phase mass ("predicted SOA-22 SOA"), the OFR reacted SOA-22 precursor mass was weighted with compound-specific SOA yields (Y_{SOA}) from literature, relying on the evaluation of this approach by ref.⁹. Details and a discussion of its limitations are provided in section S3 and Eq. S1. The SOA yields describe the fraction of reacted SOA precursor that condenses into the particle phase. Y_{SOA} for the three main species is 0.44 (phenol), 0.52 (naphthalene) and 0.33 (benzene) as summarized in Table 2. The value of the experimentally determined particle phase SOA mass of fresh emissions was 1.20 ± 0.81 times that of the predicted value (summing all estimated SOA contributions). For catalytically cleaned emissions, the ratio was 1.35 ± 0.73 . The method therefore underestimated the experimentally determined particle phase SOA by 20% and 35% on average.

Benzene, despite dominating the gas-phase emissions by accounting for 58-72% of the SOA-22 precursor mass (Figure 3a), finally contributed relatively less to the predicted SOA mass in the particle phase (5-25%), owing to its comparatively lower atmospheric reactivity. Instead, naphthalene and phenol together were responsible for a substantial fraction (55-71%) of the predicted SOA in the OFR experiments, including 30-38% derived from naphthalene and 25-33% from phenol (Figure 3c/Figure S7). An additional 3-7% of the SOA formation was attributed to cresol, 2-6% to styrene and 2-3% to benzaldehyde. Catalytic abatement of phenolic compounds and naphthalene should therefore substantially reduce the observed SOA mass, as we confirm in the next section.

Figure 3. Relative contributions of SOA-22 ($\mu\text{g m}^{-3}$). a) fresh gas-phase composition based on the PTR-ToF-MS sum of SOA-22 (experiments E5/E6 and E3/E4, E7, E8 and E9/E10), b) photo-chemically aged, i.e. OFR reacted gas-phase (E6, E4, E10), c) "predicted SOA-22 SOA" relying on published SOA yields⁹ (E6, E4, E10).

SOA reduction. Figure 4 presents the effect of a catalytic converter on the SOA formation. We observed a substantial reduction of SOA formation upon catalytic cleaning of the emissions. As the fraction of converted NMHC and SOA-22 precursors increased with catalyst temperature, SOA formation decreased. In the case of Pt/Al₂O₃, SOA was significantly reduced at temperatures as low as 185°C (by 68%). For Pt/CeO₂-Al₂O₃, SOA reduction was almost complete (>97%) at 310°C, and likewise significant at the lower temperatures, reaching 62% reduction at 185°C.

Figure 4. Secondary organic aerosol (SOA) formation. a) Fresh emissions (i.e. without catalyst, “w/o cat.”) and emissions cleaned at specific temperature set-points of the catalytic monoliths are presented. Pt/Al₂O₃ at 185°C (E6), Pt/CeO₂-Al₂O₃ at 185 to 310°C (E4 and E10). Fresh emission SOA was measured in duplicate (average±1SD are 519±3 (E6), 641±20 (E4), 1001±15 (E10) µg m⁻³). b) SOA reduction, NMHC reduction and “SOA-22 precursor” reduction of catalytically cleaned compared to fresh emissions.

The experimentally measured SOA reduction was linked to a) NMHC reduction, b) SOA-22 precursor reduction and c) reduction of “predicted SOA-22 SOA” in Figure 5 (Figure S8 gives further details). The SOA reduction coincided with the removal of only a small fraction of the NMHC, such as 3 to 10% of the FID-based NMHC signal below 185°C, and 60 to 80% at 310°C. At this temperature SOA was almost completely removed (Figure 5a). The NMHC signal by itself is therefore an insufficient predictor for SOA mass reduction. Instead, the summed SOA-22 precursor reduction describes the measured SOA reduction better (Figure 5b).

Compounds within the SOA-22 sum contribute to the SOA mass at distinct fractions that differ from their gas-phase contributions. As detailed in the previous section, these fractions are a function of 1) the precursors' abundance, 2) the actual OFR reacted mass (i.e., essentially corresponding to the compounds' abundance weighted by its k_{OH}), and 3) the SOA yield. Therefore, only a comparison of the experimentally measured SOA reduction with the reduction of “predicted SOA-22 SOA” yields a relationship close to 1:1 (Figure 5c). Partitioning effects⁶⁵⁻⁶⁷ play an additional role in the observed SOA reduction assessment and add uncertainty to our analysis (see our discussion in SI section S3, Table S2 and Figure S9 for further information).

A substantial fraction (55-71%) of the SOA mass is attributed to naphthalene and phenol. Although their complete removal would reduce the SOA-22 precursor mass only by 17-21%, a particle phase SOA-22 SOA mass reduction of 55-71% would be achieved. Indeed, phenol and naphthalene are significantly abated by the catalytic converters. At low catalyst temperatures, a particular impact on the SOA reduction may be assigned to the effective removal of phenolic compounds, given that at 185°C, their abatement was >95%, while naphthalene abatement remained below 35% (Figure 2). While the removal of 95% of phenol results only in a SOA-22 precursor reduction of 6-9%, a reduction of 24-31% of the predicted SOA-22 SOA mass can be achieved. Naphthalene abatement by 35% instead translates into a SOA-22 precursor reduction of ~4% and a corresponding predicted SOA mass reduction of 11-13%.

Figure 5. Secondary organic aerosol (SOA) reduction. a) SOA reduction vs. NMHC reduction. NMHC is derived from Figure 1, as it is not directly accessible in E6, E4 and E10. See Figure S6 for CO conversion points). b) SOA reduction vs. "SOA-22 precursor" reduction, c) SOA reduction vs. "predicted SOA-22 SOA" reduction Figure S8 presents additionally FID-based NMHC vs. PTR-ToF-MS-based "SOA-22 precursor" reduction, and "SOA-22 Precursor" vs. "Predicted SOA-22 SOA" reduction.

In sum, the SOA-22 precursor reduction is 10-13% and the expected SOA reduction 35-45%. Instead, removing 10-13% benzene from the SOA-22 precursors would result in maximal SOA mass reduction of 10%. Effective removal of atmospherically reactive compounds with high SOA yields at the lower catalyst temperatures is therefore a crucial aspect in the SOA reduction. It results in a gradually less efficient precursor composition in terms of SOA formation (lower k_{OH} and lower yield) as a function of catalyst temperature.

Implications

Our results demonstrate the effective removal of critical emissions constituents such as toxic CO and harmful aromatic hydrocarbons, using catalytic converters. This significantly lowers the health impact as well as the SOA formation potential of wood burning emissions. Through reduced SOA formation, the total particulate matter pollution can be reduced substantially considering the high POA/BC and high SOA/POA ratios reported for log wood burning.^{6, 9} Low catalyst light-off temperatures are crucial, because appliances emit large fractions of VOC and harmful aromatic compounds during start-up phases, re-fueling and burn-out, when the exhaust temperature is relatively low, and when also stove automatization has limited effects to reduce emissions.^{3, 20, 25, 27, 28,}

⁶⁸ Both, CO and SOA precursors, are effectively removed at sufficiently low temperatures in our experiments, supporting also the application of cheaper catalytic materials than Pt in the future. Instead, the reduction of methane, which should be abated owing to its high global warming potential, requires tailored catalysts. CeO₂ has the potential to lower the required conversion temperatures. Alternately, installation in the burner chamber could be considered to reach higher temperatures, but catalyst stability may become an even bigger challenge under such conditions. This requires attention in research and development projects. The overall technical applicability (such as clogging and issues with pressure drops) remains to be investigated. Installations of catalytic converters downstream of an electrostatic precipitator²⁷ may be an effective strategy to minimize catalysts' exposure to particulate matter for long-term operation. Also engineering optimization allowing for higher pressure drops, such as optimized dimensions and the use of flue gas fans, offer to overcome technical constraints and may support long-term operation for catalytic gas cleaning systems as presented here, and potentially also the catalytic removal of primary particulate matter presented elsewhere^{31, 35-37}.
