Abstract: Multiferroics have attracted strong interest for potential applications where electric fields control magnetic order. The ultimate speed of control via magnetoelectric coupling, however, remains largely unexplored. Here we report on an experiment in which we drive spin dynamics in multiferroic TbMnO₃ with an intense few-cycle terahertz (THz) light pulse tuned to resonance with an electromagnon, an electric-dipole active spin excitation. We observe the resulting spin motion using time-resolved resonant soft x-ray diffraction. Our results show that it is possible to directly manipulate atomic-scale magnetic structures using the electric field of light on a sub-picosecond timescale.

Main Text: Data storage devices based on ferromagnetic or ferroelectric materials depend strongly on domain reorientation, a process that typically occurs over time scales of several nanoseconds. Faster reorientation dynamics may be achievable using intense electromagnetic (EM) pulses (1). The EM pulses can couple to magnetism either indirectly via electronic excitations (2) or directly via the Zeeman torque induced by the magnetic field (3-5). Direct excitation has the advantage of minimal excess heat deposition, but requires frequencies in the 10^{10} - 10^{12} Hz range. The low magnetic field strength of currently realizable THz frequency EM sources poses a formidable challenge for such schemes.

Thanks to the coexistence of different ferroic orders, multiferroics offer new routes to domain control (6). Particularly strong coupling between the ferroelectric and magnetic order exists in single-phase frustrated magnets where noncollinear spin structure drives ferroelectricity as a result of weak relativistic interactions (7-9). Consequently, the magnetic order can be

controlled by application of an electric field (10-13). The speed of domain switching triggered by simple step-function-like electric fields appears, however, to be limited to a timescale of several milliseconds (14). As an alternate solution, optical pulses have been shown to affect the magnetic structure of multiferroics on a femto- and picosecond timescale (15-17). It has been predicted that ultrafast magnetic dynamics can be also triggered by coherent excitation of electromagnons, electric-dipole active spin excitations directly connected to the magnetoelectric coupling (18). Here we show experimentally that a few-cycle THz pulse tuned to resonance with an electromagnon can transiently modify the magnetic structure of multiferroic TbMnO₃.

TbMnO₃ is a model spin-cycloid multiferroic exhibiting strong magnetoelectric coupling. Although it has a relatively simple perovskite atomic structure, a strong GdFeO₃-type distortion gives rise to a variety of spin-frustrated phases (19, 20). At room temperature, the crystal is paramagnetic. Below 42 K the Mn spins form a paraelectric sinusoidally modulated spin density wave (SDW) state which transforms into a spin-cycloid state below 27 K. In this phase the spins form a cycloid within the (*bc*) crystallographic plane (Fig. 1A) and a spontaneous ferroelectric polarization along the *c* axis develops. Microscopically, the spin current between canted spins on neighboring sites *i, j* gives rise to a ferroelectric polarization $p_{ij} \propto r_{ij} \times (S_i \times S_j)$ (7), and the magnitude of the polarization is further enhanced by lattice displacements (21-23). In all these spin frustrated phases the magnetic structure of the Mn spins is incommensurate with the lattice, characterized by a wave vector $\mathbf{k} = (0, q, 0)$, where $q \approx 0.28$ changes very slowly in the SDW phase with temperature (24).

The EM excitation spectrum of TbMnO₃ shows broad peaks in the THz frequency range; these have been assigned to electromagnons (25-29) (Fig. 1B, lower inset). The strongest feature at 1.8 THz is activated with the electric component of light parallel to the *a* axis and is absent in

other geometries (26). It has been proposed that the oscillating electric field along the a axis modifies the nearest neighbor ferromagnetic exchange constant in the (ab) plane, resulting in anti-phase spin oscillations within the spin cycloid plane (28, 30). Weaker spectral features at lower frequencies have been proposed to arise from the higher harmonics of the spin cycloid and coupling to the strongest electromagnon (30), and from out-of-plane spin cycloid motions (28, 31, 32).

To investigate whether excitation of electromagnons in TbMnO_3 is a viable route for magnetic order control, we performed a THz pump and soft x-ray probe experiment (Fig. 1B). The sample is a single crystal of TbMnO_3 cut to the (010) surface, oriented so that the a axis is at 45° with respect to the horizontal scattering plane. We generated few-cycle, phase stable THz pulses with a center frequency of 1.8 THz using optical rectification in a nonlinear organic crystal with a peak electric field of approximately 300 kV/cm at focus (33). We measured the electric field component of the THz waveform at the sample position using electro-optical sampling. To see the spin motion resulting from the excitation we used time-resolved resonant soft x-ray diffraction at the Mn L_2 edge and measured the intensity of the first order $(0q0)$ cycloid reflection (34).

The spin dynamics can be extracted from the behavior of the intensity of the $(0q0)$ diffraction peak as a function of pump-probe delay time $\Delta\tau$ (Fig. 2). At $T = 13$ K, where TbMnO_3 is deep in the multiferroic phase, the x-ray signal shows oscillations resembling the shape of the THz pump pulse electric field (Fig. 2A). The observed modulation of the diffraction peak intensity is over an order of magnitude larger than expected for unconstrained spin precession driven directly by the magnetic field component of the THz pulse (34). The Fourier transform of the x-ray trace (Fig. 2D) shows that the material response has essentially the same

frequency spectrum as both the pump and the electromagnon. The delay between the first maximum of the pump trace and the first maximum of the x-ray trace is 250 fs, corresponding to approximately half of a single oscillation cycle. Inverting the sign of the electric field of the pump pulse results in an opposite sign of changes in the diffraction intensity transients (Fig. 2B). Such behavior is expected when it is the electric field, and not simple heating, that drives the spin motion. When TbMnO_3 is in the non-multiferroic SDW phase ($T = 30$ K), the oscillation in the peak intensity following the pump is strongly suppressed (Fig. 2C). This temperature dependence gives strong evidence that the THz-induced spin motion is correlated with the presence of multiferroicity. At 30 K we tentatively attribute the slight drop of overall intensity after the pump to heating effects from absorption of the THz pulse, which leads to an estimated temperature increase of less than 0.05 K (34).

To better understand the time dependence of the spin response, we construct a very simple model of the system as two independent simple harmonic oscillators at the electromagnon resonance frequencies of 0.7 THz and 1.8 THz (34). Although not a perfect match to the data, the behavior of the conjugate momentum of the higher frequency oscillator successfully reproduces the general shape of the oscillation and the delay between the driving electric field and the changes in x-ray diffraction (Fig. 2A and 2B). The agreement is much worse for either canonical coordinate of the lower frequency oscillator, suggesting that off-resonant excitation of the lower energy electromagnon or other purely magnetic modes is not consistent with the measured shape or delay of the response (34).

Resonant x-ray scattering at the Mn L -edge is predominantly sensitive to the magnetic moment of the Mn $3d$ shell (35). An analysis of how different spin motions contribute to the intensity of the diffraction peak allows us to test which of them are involved in the observed

oscillations. We consider two components of the induced spin motion, motivated by the current understanding of spin dynamics in this system. In the first component the spins move in antiphase within the spin cycloid plane, the pattern widely considered to be responsible for the infrared activity of the 1.8 THz electromagnon (28). The driving electric field applies an effective “force” to this component. In our model of the electromagnon as a harmonic oscillator, this component of the spin motion should then be identified with the “position” of the oscillator. In the proposed pure spin Hamiltonian for this system (18), the conjugate momentum must be a spin motion orthogonal to this position coordinate. Numerical simulations based on this Hamiltonian have predicted that a sufficiently intense THz pulse in resonance with the 1.8 THz electromagnon can induce coherent rotation of the spin cycloid plane about the b axis until it reaches another stable orientation in either the (ab) or (bc) plane (18). In our experiment the effective THz pulse field strength is over two orders of magnitude lower than used in these simulations (34) and so we do not expect to see a persistent domain reorientation. Instead, we propose to consider a smaller rotation of the spin cycloid plane about the b axis as a second component of the spin motion that corresponds to the conjugate momentum for the 1.8 THz resonance.

We model these two spin motion patterns separately as distortions to the equilibrium magnetic structure which influence the magnetic structure factor (34). We then calculate the intensity of the $(0q0)$ diffraction peak as a function of each coordinate of the spin motion (Fig. 3). For the in-plane motion the intensity of the diffraction peak is an even function of the spin coordinate, giving a decrease of the diffracted intensity with twice the frequency of the spin motion (Fig. 3A). For the spin cycloid plane rotation, the change of diffracted intensity is an odd function of the rotation angle. This motion then leads to a modulation of the diffraction intensity

with the same frequency as the spin motion (Fig. 3B). For a field-driven excitation process we expect the spin motion frequency to be the same as the frequency of THz pump. We conclude that the main motion visible in our experiment is a rotation of the spin cycloid plane. The in-plane spin motion may also be present, but its response would be suppressed at the current experimental time resolution. This is consistent with our harmonic oscillator model, which suggests that we see primarily dynamics of the conjugate momentum of the resonance.

For π -polarized x-rays at the Mn L_2 edge the scattering intensity is a strongly varying function of the sample azimuth (rotation about the Bragg wave vector) (34). Rotation of the spin cycloid plane about the b axis induced by the THz pulse is equivalent to rotating the sample about the $(0q0)$ scattering vector. Hence we interpret the data quantitatively by comparing the change of the intensity of the diffraction peak seen in the pump-probe trace with the change seen upon rotating the sample by a small angle around the azimuth of 45° in equilibrium conditions (Fig. 4). We estimate that the observed $(1.35 \pm 0.12)\%$ maximum change of peak intensity corresponds to an amplitude of spin cycloid plane rotation equal to $(4.2 \pm 0.4)^\circ$ (34). We expect higher fields will lead to larger spin cycloid rotations. A simple linear extrapolation suggests that THz pulses with an amplitude of 1-2 MV/cm inside the sample could lead to spin cycloid rotations on the order of 90° . We can compare this against the model of Ref. (18), which predicts switching at 14-15 MV/cm for single-cycle THz pulses.

Our results show that intense THz pulses can modify the magnetic order in a multiferroic. Given that TbMnO_3 is a model compound for a large group of materials with noncollinear spin order, our results serve as a proof-of-principle for a wide range of compounds. Moreover, the presence of magnetoelectric coupling in multiferroic heterostructures encourages a search for similar mechanisms as a basis for technologically feasible multiferroic devices.

Materials and Methods

Sample preparation

A high quality, stoichiometric TbMnO₃ single crystal was grown by the optical floating zone technique at the zoning rate of 0.5 mm/h with rotation rate of 15 rpm for the growing crystal and 0 rpm for the feed rod under static argon. The crystal was oriented using Laue backscattering and cut to expose the (010) face with an approximately 3° miscut. The surface of the sample was polished and afterwards the sample was annealed in air in 650°C for 110 h. The dimensions of the crystal are approximately 2 mm x 2 mm x 3 mm.

The *Pbnm* orthorhombic convention is used to describe the crystal axes.

Experimental setup

The setup is sketched in the Fig. S1. The experiment was performed at the Soft X-Ray (SXR) beamline at the Linac Coherent Light Source X-ray Free Electron Laser (LCLS FEL) (36), using the Resonant Soft X-ray Scattering endstation (37). The diffraction peak was measured using the fast-CCD camera (fCCD) (37).

The FEL was operated at a repetition rate of 60 Hz. The x-ray absorption spectrum of TbMnO₃ at 15 K was measured around the Mn *L*₂ edge in order to calibrate the incident x-ray energy. The (0*q*0) peak was measured in the in-plane scattering geometry using π -polarized x-ray pulses with duration of 100 fs FWHM. Previous work on this system under equilibrium conditions has shown using x-ray polarization analysis that the dominant scattering contribution for this diffraction peak is magnetic in origin (38). Kirkpatrick-Baez optics were used to focus the beam to a spot size with a diameter of 300 μ m.

We used a high power Ti:Sapphire laser synchronized with the FEL trigger to produce 120-fs long pulses with a center wavelength of 800 nm. The main beam was split into three branches: (1) a branch leading to the high-power Optical Parametric Amplifier (OPA), used later to generate the THz pulses, (2) a branch hitting the sample collinearly with the x-rays, used for alignment and timing purposes, and (3) a branch used to determine the mutual time jitter of the x-ray and laser pulses. The x-rays, 800 nm beam and the THz beam entered the sample collinearly.

THz generation and characterization

The phase-stable, THz pulses were generated using the organic crystal 4-N,N-dimethylamino-4'-N'-methyl-stilbazolium 2,4,6-trimethylbenzenesulfonate (DSTMS) (39), with a diameter of 6 mm and thickness of 0.59 mm. The DSTMS crystal was pumped with IR pulses with a center wavelength of 1500 nm and a duration of approximately 120 fs FWHM. The THz pulses were polarized horizontally and hit the sample with p-polarization. Inverting the sign of the THz waveform was achieved by rotating the DSTMS crystal by 180° around the beam propagation direction. The THz beam was focused on the sample using an off-axis parabolic mirror placed inside the RSXS chamber. The THz spot size at focus had a $1/e^2$ diameter of approximately 750 μ m.

The shape of the THz waveform was measured using electro-optical sampling (40) on the optimally oriented 150 μ m thick GaP crystal on 2 mm thick GaP substrate, placed

in the position of the TbMnO₃ sample. The maximal modulation of approximately 45% of the electro-optical signal measured with the balanced photodiode corresponds to an amplitude of the electric field of the THz pulse of 300 kV/cm, assuming an electro-optic coefficient of GaP $r_{41} = 0.88$ pm/V and refractive indices of GaP $n_{800nm} = 3.2$, $n_{THz} = 3.34$ (41, 42). Although the absolute sign of the electric field is ambiguous in our measurements, relative changes in the sign of the field on rotating the DSTMS crystal by 180° are well characterized.

Because of the Bragg scattering geometry, the THz beam was incident on the surface of TbMnO₃ at an angle of approximately 63°. The amplitude of the component of the electric field of the THz along the a axis inside the sample is estimated to be 65

kV/cm, using $E_{||a} = 1/\sqrt{2} \cdot t_p(\theta_{inc}) \cdot \cos(\theta_{tr}) \cdot E$, where $t_p = 0.31$ is the Fresnel transmission coefficient for the p-polarized field with amplitude E at the incident angle of $\theta_{inc} = 63^\circ$, and θ_{tr} is the angle between the direction of propagation of the refracted beam and the surface normal. In these calculations we use only the real part of refractive index of TbMnO₃ at 1.8 THz, $n = 4.31$, assuming it is equal along a and c axes (26, 43).

The temperature rise of the sample in the sinusoidal phase is calculated assuming that all the energy of the incident THz pulse is absorbed by the sample and converted to heat. We assume that all the incident THz radiation is absorbed ($T_p(63^\circ) = 0.89$) and that the heat capacity of TbMnO₃ equals to 14 Jmol⁻¹K⁻¹ at 30 K (19). The THz penetration depth in the SDW phase is estimated to be approximately 60 μm at 1.8 THz, assuming that the real part of the refractive index is approximately the same in the multiferroic and the SDW phase (26, 43).

Overlap and timing

The x-ray penetration depth (0.06 μm at 652.8 eV) is much smaller than the THz penetration depth (approximately 15 μm at 1.8 THz in the multiferroic phase of TbMnO₃ calculated using the imaginary part of the refractive index (43)). Spatial overlap between the x-ray and 800 nm beams was achieved imaging the x-ray induced fluorescence from a YAG crystal moved to the sample position. The time overlap between the x-ray and THz pulses was obtained in a two-step process using an intermediate overlap with the 800 nm beam. First, we found overlap in time between the x-ray and 800 nm pulses in an x-ray pump, 800 nm probe experiment using 500 μm thick ZnTe crystal placed in the position of the TbMnO₃ sample. Soft x-rays excite carriers in ZnTe, inducing a sudden drop in transmittivity of the optical beam, which allows determination of time zero. Afterwards, spatial and temporal overlap between the 800 nm beam and the THz were established using electro-optical sampling on a GaP crystal moved to the sample position. We estimate the accuracy of time zero determination to be 25 fs from uncertainties in the measurement, assuming that the optical response of ZnTe to x-ray excitation is an ideal step function in the limit of zero pulse duration.

The delay time between the x-rays and the THz was changed using a continuously moving encoded mechanical delay stage put in the branch of 1500 nm beam (DL1 on Fig. S1). For every FEL shot, the jitter between the x-ray pulse and the main 800 nm pulse was monitored using a time-to-space mapping cross-correlator (44), resulting in an effective time resolution of approximately 250 fs FWHM.

Data collection and analysis

For each shot we extract the intensity of the diffraction peak, the time delay between the pump and the probe and the intensity I_0 of the incident x-ray beam. The intensity of the diffraction peak is calculated by integration within a set region of interest on the image from the fCCD. For each shot the image is corrected for the inherent background of the camera by subtracting the background frame recorded before every data run, and for the short-time-scale drift of the overall readout from the camera by subtracting the intensity integrated within the region of interest placed far away on the detector from the diffraction peak. The relative incident x-ray pulse intensity is determined for each shot by measuring the photoelectron current from an aluminum-coated foil placed in the beamline (36).

Because the optical delay stage was scanned continuously, the total number of shots contributing to a single data point is different. For data in Fig. 2A the total number of shots per data point around time zero is approximately 12 000, while for data in Fig. 2B-C it is approximately 5 000. We cut off the delay time at the bin where the number of shots per data point drops to half of the value around time zero.

To account for large fluctuations of the x-ray pulse intensity, we use a weighted average to obtain diffraction intensity for one bin for every data run, where we weight the diffraction intensity by the corresponding value of the I_0 for all shots. To correct for nonlinearities in I_0 readout we use a calibration curve, created by plotting the diffraction intensity as a function of I_0 and fitting it with a second order polynomial. We assume that the diffraction efficiency of the sample is a function well-described by simply a fraction of incident x-ray intensity and that the readout from the fCCD detector is linear as a function of intensity of the diffraction peak, which is well supported by the fact that the shape of the diffraction peak on the detector barely changes as a function of the x-ray intensity.

In order to calculate the error bars of the pump-probe traces, we split the data runs contributing to a single measurement into slices consisting of approximately 10 000 shots each. For every slice, we extract a pump-probe trace by time-binning the data in 50-fs wide bins. Because the diffraction efficiency of the sample changes with time, we normalize the trace from every slice to the value of the signal before time zero. The traces from separate slices are then averaged to obtain the final pump-probe trace and the error bars for every bin are calculated as a standard error within each bin. For data in Fig. 2A, 2B and 2C the number of slices was approximately 70, 20 and 30 respectively.

The uncertainties for the Fourier-transformed spectra are calculated following (45).

Supplementary Text

Modeling the material response with a harmonic oscillator model

We model the system as a collection of two types of uncoupled, damped harmonic oscillators. The response in this region of the electromagnetic spectrum is dominated by two types of resonators with frequencies near 0.75 THz and 1.8 THz. Let q_1 and p_1 be the “position” and “momentum” canonical coordinates for the lower energy oscillator. Similarly, let q_2 and p_2 be the canonical coordinates for the higher energy oscillator. The full dynamics are then given by a system of four first order ordinary differential equations

$$\frac{dq_j}{dt} = p_j$$

$$\frac{dp_j}{dt} = f_j(t) - 4\pi\zeta_j\nu_j p_j - 4\pi^2\nu_j^2 q_j$$

where ν_j and ζ_j are the natural frequency and damping for each oscillator, and $f_j(t)$ is the driving force which we assume here is proportional to the electric field of the applied THz pulse. The solutions in the Fourier domain are

$$Q_j(\nu) = \frac{F_j(\nu)}{4\pi^2(\nu_j^2 - \nu^2 - 2i\zeta_j\nu_j\nu)}$$

$$P_j(\nu) = \frac{i\nu F_j(\nu)}{2\pi(\nu_j^2 - \nu^2 - 2i\zeta_j\nu_j\nu)}$$

where Q_j , P_j and F_j denote the Fourier transforms of q_j , p_j and f_j . Since the imaginary part of the dielectric permittivity ε is proportional to a weighted sum of the imaginary parts of $Q_1(\nu)$ and $Q_2(\nu)$, we can use the published permittivity data (26) to estimate $\nu_1 = 0.75$ THz, $\nu_2 = 1.85$ THz, $\zeta_1 = 0.34$ and $\zeta_2 = 0.198$. The resulting fit is shown in Fig. S2A.

Upon inverse Fourier transform, we can then compare our model, one mode at a time, with the recorded time-domain material response. In Figs. S2B and S2C we plot both $q_j(t)$ and $p_j(t)$ for each oscillator. These curves are each scaled by a constant, adjusted individually to best match the data. For p_1 and p_2 the scaling constants are negative, an allowance for the ambiguity in the absolute sign of the effective force on the oscillator. These scaling factors are the only adjustable fit parameters in the model. As seen in Fig. S2B, $p_2(t)$ fits the data reasonably well, recovering the correct phase delay between the pump and observed x-ray oscillation. Neither $q_1(t)$ nor $p_1(t)$ reproduce the experimental data well, both reacting significantly earlier in time than the measured spin response. The “delay” with response to the driving field observed in the data is in fact a direct consequence of driving the oscillator in resonance. In resonance, energy is efficiently transferred to the oscillator and stored there until the natural damping effects lead to a decay of the coherent response. The fact that we observe this delay is also evidence that the observed dynamics are not related to the non-resonant excitation of other, purely magnetic resonances in system that we have not considered here.

RSXS intensity resulting from spin motion patterns

The azimuthal scans of the $(0q0)$ peak at the Mn L_2 edge were measured in a separate experiment at the RESOXS endstation at the SIM beamline (Swiss Light Source, PSI) (46) for π - and σ -polarized incident x-rays without the analysis of the diffracted beam polarization (Fig. S3) (38). The calculation of the Fourier coefficients of the magnetic structure of TbMnO₃ in the multiferroic phase contributing to the $(0q0)$ peak visible in the resonant scattering experiment is performed using the program BasIreps 4.10 included in the FULLPROF suite. In the multiferroic phase two irreducible representations are required to describe the magnetic structure (20). The values of the components of the basis functions along the b and c axes are obtained from the fit to the experimental data (solid lines in Fig. S3). For the magnetic structure factor of a form $\mathbf{f}_{0q0}^0 = (0, \nu, w)$ we obtain $\nu = 0.57i$ and $w = 1$. The directions and amplitudes of the contributions of magnetic moments visible in the experiment are then calculated from the

Fourier coefficients. Our data are consistent with the cycloid propagating along the b axis, however the Mn spin components along the c axis we observe at this particular reflection are ordered ferromagnetically along the c axis. The resonant x-ray diffracted intensity and the shape of the azimuthal scans are calculated numerically following Ref. (47) confirming a good agreement with the experimental data.

In the next step, the magnetic structure is deformed by rotating the spins on particular sites by an angle $\pm\varphi$ ($\pm\varphi'$), in order to reproduce the magnetic structure during the spin excitation in a state “frozen” in time. For every φ (φ'), we compute the magnetic structure factor of the resulting distorted magnetic structure. The intensity of the $(0q0)$ diffraction peak at azimuth of 45° and π -polarized incident x-rays is then calculated and normalized to the value obtained for $\varphi=0$ ($\varphi'=0$) (the case of non-distorted cycloid).

Estimate of magnetic-field induced dynamics

To estimate the maximal effect of the non-resonant oscillating magnetic field component of the THz excitation on the observed x-ray diffraction, we consider the unconstrained precession of the spin magnetic moments $\mathbf{S}_i$ given by

$$\frac{d\mathbf{S}_i}{dt} = -\gamma \mathbf{S}_i \times \mathbf{B}(t)$$

where $\mathbf{B}(t) = \mathbf{B}_0 g(t)$ is the applied magnetic field, $\gamma = 1.76 \cdot 10^{11}$ rad / T s is the gyromagnetic ratio, $\mathbf{B}_0$ is the magnitude and direction of the magnetic field, and $g(t)$ gives its time dependence. Assuming the changes in spin direction are small, to leading order we integrate to obtain

$$\mathbf{S}_i(t) \approx \mathbf{S}_i^0 - \gamma \mathbf{S}_i^0 \times \mathbf{B}_0 \int_{t_s}^t g(t') dt'$$

where $\mathbf{S}_i^0$ is the initial spin orientation at a time t_s well before the THz pulse interacts with the system. Since this relation is linear in $\mathbf{S}_i^0$ and the Fourier transform of the spin density is also a linear operation, the time-dependent magnetic structure factor $\mathbf{f}_{0q0}(t)$ has the same form

$$\mathbf{f}_{0q0}(t) \approx \mathbf{f}_{0q0}^0 - \gamma \mathbf{f}_{0q0}^0 \times \mathbf{B}_0 \int_{t_s}^t g(t') dt'$$

Using the value of the magnetic structure factor $\mathbf{f}_{0q0}^0$ inferred from the equilibrium measurements, we then calculate the effect on the diffracted intensity (47). For the 0.1 T peak fields used in our experiment we estimate a maximum change in the diffracted intensity of 0.035%, well below the modulations we observe. We also note that the integral term in the time dependence would lead to a phase lag of 90° in the response, which is also counter to observation.

Fig. S2

(A) Measured $\text{Im}[\epsilon\mu]$ from ref. (26) compared to the fitted results from the model discussed in the text. (B) The simulated responses of the 1.85 THz mode. (C) The simulated responses of the 0.75 THz mode. In each plot red is the electro-optic THz trace, blue circles indicate the measured response, and the calculated responses $q_j(t)$ and $p_j(t)$ are shown as dashed and solid lines, respectively. The amplitudes of the simulated responses are individually scaled to best match the experimental data.

Fig. S3

Dependence of the $(0q0)$ diffraction peak intensity on the azimuthal angle for the π - and σ -polarized incident x-rays (filled black and open red symbols, respectively), without outgoing x-ray polarization analysis. The azimuthal angle is defined to be zero when the a axis is in the horizontal plane. Solid lines show the fit to the data. The uncertainties are smaller than the symbol size.
