In order to elucidate the magnetic ground state of Sr2VO4, we have measured muon spin rotation and relaxation ($\mu^+\text{SR}$) spectra of a powder sample in the temperature range between 1.8 and 140 K. As a result, we have clarified that the transition at 105 K is not magnetic but structural and/or electric in origin and found the appearance of static antiferromagnetic (AF) order below 8 K. Moreover, the distribution of the internal AF field was found to be very broad, even at the lowest temperature measured. These results are consistent with the formation of an orbital-stripe order with collinear AF order for the magnetic ground state of Sr2VO4.

DOI: 10.1103/PhysRevB.89.020402 PACS number(s): 75.25.Dk, 75.50.Ee, 75.70.Tj, 76.75.+i

Tetragonal Sr2VO4 with a K2NiF4-type structure has been considered as an analog of a parent compound of the first superconducting cuprate, i.e., La2CuO4, since the electron configuration of the V4+ ion is $t_{2g}$ with $S = 1/2$ in a tetragonal crystal field of a VO6 octahedron [1–7]. Although susceptibility ($\chi_m$) measurements clearly show a magnetic anomaly at 105 K (= $T_c$) [6], a past neutron diffraction study reported the absence of magnetic peaks even at 5 K [2]. Since x-ray diffraction studies revealed a sudden enhancement of the $c/a$ ratio below $T_c$ [6], it was proposed that an orbital-ordering transition occurs at $T_c$. In fact, first principles calculations predicted an antiferromagnetic (AF) and orbital-ordered state with a nontrivial and large unit cell structure in the ground state, because of the coexistence and competition of ferromagnetic and AF exchange interactions [8,9].

Recently, a more exciting possibility was proposed, namely, that a hidden magnetic order is induced by spin-orbit coupling for a $t_{2g}$ electron system [10]. Such work also predicted an unconventional magnetic octupolar ordering at low $T$ for Sr2VO4. Furthermore, alternating spin-orbital order in the $ab$ plane was proposed by considering the effects of spin-orbit coupling, crystal field, and superexchange on the energy levels of the V4+ ions [11].

Despite the above attractive predictions, there are few reports on Sr2VO4 utilizing microscopic magnetic techniques [12]. Macroscopic magnetic measurements such as $\chi_m$ and neutron scattering usually give us significant insight into the ground state of magnetically ordered solids. However, such techniques are sometimes not suitable, particularly for the materials exhibiting order with a broad field distribution, i.e., when short-range order, random, or nearly random order appears in a material, due to the absence of periodic structure and/or the presence of rapid fluctuations. In contrast, the muon spin rotation and relaxation ($\mu^+\text{SR}$) technique is very sensitive to local magnetic environments with a different time window compared to neutron scattering; thus $\mu^+\text{SR}$ has provided crucial information on the magnetic ground state of materials [13,14]. We have therefore performed a $\mu^+\text{SR}$ experiment on Sr2VO4 and found the appearance of magnetic order not below $T_c$ but below 8 K.

A powder sample of Sr2VO4 was prepared from a precursor orthorhombic $\beta$-Sr2VO4 [15], which was made from a stoichiometric mixture of SrO, V2O3, and V2O5 by a solid state reaction at 1400 °C in an Ar gas flow for 12 h. SrO was obtained by thermal decomposition of SrCO3 at 1100 °C for 12 h under vacuum, and V2O3 was prepared from V2Os by reduction in an H2 gas flow at 600 °C for 4 h, and then at 800 °C for 2 h. The obtained precursor was sealed in an Au capsule and then heated at 1300 °C under 4 GPa.

Powder x-ray diffraction (XRD) analyses revealed that the obtained sample was almost single phase of a K2NiF4-type structure with $I4/mmm$ space group [2]. Sr1.5V2O5 was present in the sample at a level below 2%. This suggests that the average valence of the V ion in the whole sample is above 4+, implying the absence of oxygen deficiencies in Sr2VO4. $\chi_m (=M/H$, where $M$ is magnetization) was measured below 400 K under a $H < 10$ kOe field with a superconducting quantum interference device (SQUID) magnetometer. (See Fig. 1.) A Curie-Weiss fit in the $T$ range between 110 and 320 K provided the $T$-independent term $\chi_0 = 0.00007(2) \text{emu/mol}$, Weiss $T$ [$\Theta_{CW} = -28(4)$ K], and effective magnetic moment ($\mu_{eff} = 1.36(2)\mu_B$). These values are consistent with the literature [1–5].

Figures 2(a) and 2(b) show the zero field (ZF) and longitudinal field (LF) $\mu^+\text{SR}$ spectra at 1.8 K. Here LF means the field is parallel to the initial muon spin polarization ($S_0$). The ZF spectrum exhibits rapid damping with a first minimum at $t \sim 0.25 \mu$s, indicating the presence of a broad

* e0589@mosk.tytlabs.co.jp
distribution of internal fields \(H_{\text{int}}\). Since the LF clearly decouples the damping, the ZF and LF spectra are likely to be fitted by a dynamic Gaussian Kubo-Toyabe function \(G_{\text{KT}}\) due to random \(H_{\text{int}}\)'s at the muon sites [16]. However, two additional exponentially relaxing signals are required in order to reproduce the spectra, that is,

\[
A_0 P(t) = A_{\text{KT}} G_{\text{KT}}(\Delta, \nu_{\text{fuct}}, T, H_{\text{L}}) + A_F e^{-\lambda_F t} + A_S e^{-\lambda_S t},
\]

where \(A_0\) is the initial asymmetry, \(P(t)\) is the muon spin depolarization function, \(A_{\text{KT}}\), \(A_F\), and \(A_S\) are the asymmetries associated with the three signals, \(G_{\text{KT}}(\Delta, 0, t, 0) = 1/3 + 2/3(1 - \Delta^2 t^2) \exp(-\Delta^2 t^2/2)\), \(\Delta\) is the field distribution width at the muon site, \(\nu_{\text{fuct}}\) is the fluctuation rate of the local fields responsible for \(G_{\text{KT}}\), and \(\lambda_F\) and \(\lambda_S\) are the exponential relaxation rates.

A global fit for the spectra at 1.8 K [see Fig. 2(a)], in which we used common parameters in Eq. (1) for the ZF and two-LF spectra, yielded \(A_{\text{KT}} = 0.096(3)\) with \(\Delta = 7.8(2)\) \(\mu\text{s}^{-1}\) and \(\nu_{\text{fuct}} = 0.41(2)\) \(\mu\text{s}^{-1}\), \(A_F = 0.081(7)\) with \(\lambda_F = 20(2)\) \(\mu\text{s}^{-1}\), and \(A_S = 0.036(5)\) with \(\lambda_S = 3.2(5)\) \(\mu\text{s}^{-1}\). This implies the presence of three different muon sites in the lattice, whereas there is only one muon site in the isorotational compound \(\text{La}_2\text{CuO}_4\) [17]. Also, since \(\nu_{\text{fuct}} \ll \Delta, H_{\text{int}}\) at the site responsible for the \(A_{\text{KT}}\) signal is almost static, while those for the other two sites are dynamic even at 1.8 K. This is an inconsistent situation, even though the three sites are crystallographically equivalent, but magnetically nonequivalent.

In order to obtain acceptable results for a single muon site, the ZF spectra were finally fitted by a combination of an exponentially relaxing cosine oscillation for the quasistatic internal field and an exponentially relaxing nonoscillatory signal for the “1/3 tail” signal caused by fluctuations in the field component parallel to \(\hat{S}_\parallel\):

\[
A_0 P(t) = A_{\text{AF}} e^{-\lambda_{\text{AF}} t} \cos(\omega_{\text{AF}} t) + A_{\text{tail}} e^{-\lambda_{\text{tail}} t},
\]

where \(f_{\text{AF}}\) is the muon Larmor frequency corresponding to the AF quasistatic \(H_{\text{af}}\), \(A_{\text{AF}}\) and \(A_{\text{tail}}\) are the asymmetries of the two signals, and \(\lambda_{\text{AF}}\) and \(\lambda_{\text{tail}}\) are their exponential relaxation rates. Moreover, \(A_0 = 0.226 (= A_{\text{AF}} + A_{\text{tail}})\), which is the full asymmetry, is fixed in the whole \(T\) range below 25 K, based on weak transverse field (WTF) data at 80 K. Here we should note again that both equations represent the same physical description, i.e., the presence of quasistatic \(H_{\text{int}}\) with broad distributions.

Figure 3 shows the \(T\) dependences of the \(\mu^+\) SR parameters together with \(\chi_m\) measured at \(H = 10\) and 100 Oe. We also plot the WTF asymmetry \(A_{\text{WT}}\), which monitors the nonmagnetic volume fraction in the sample, as described later. As \(T\) increases from the lowest \(T\) measured (1.8 K), \(A_{\text{AF}}\) is almost
the ratio between field cooling (ZFC) mode with $T_f$ signal and $T_f$ signal due to applied WTF and the nonoscillatory relaxing signal caused by localized magnetic moments.

FIG. 3. (Color online) $T$ dependences of (a) the asymmetries ($A_{AF}$ and $A_{TF}$), (b) the muon spin precession frequency for the $A_{AF}$ signal ($f_{AF}$), (c) the exponential relaxation rates $\lambda_{AF}$, $\lambda_{tail}$, and $\lambda_{TF}$, (d) the ratio between $\lambda_{tail}$ and $\lambda_{AF}$ as well as $f_{AF}$ and $\lambda_{AF}$, respectively, and (e) $\chi_m (=M/H)$ for Sr$_2$VO$_4$. The data in (a)–(c) were obtained by fitting WTF $\mu^+SR$ spectra using Eq. (3). In (a)–(c), the ZF $\mu^+SR$ parameters, $A_{AF}$, $A_{tail}$, $\lambda_{tail}$, and $\lambda_{AF}$, are also plotted for comparison.

$T$ independent ($A_{AF} \sim 0.18$) until 8 K, and then suddenly drops to $\sim$0.02 and becomes $T$ independent again until 25 K. Meanwhile, as $T$ decreases from 25 K, $A_{TF}$ is roughly $T$ independent above 9 K, and then rapidly decreases down to $\sim$0 below 9 K. The $A_{AF}(T)$ and $A_{TF}(T)$ curves suggest that $T_N = 9.2$ K, at which $A_{AF}/A_0 = A_{TF}/A_0 \sim 0.5$.

On the contrary, as $T$ increases from 1.8 K, $f_{AF}$ decreases with increasing slope of $df_{AF}/dT$ and disappears at $\sim$8 K. Although $T_N = 9.2$ K by the asymmetry data, the oscillatory signal, which indicates the formation of static long-range magnetic order, disappears above 8 K due to the large relaxation of a signal below the vicinity of $T_N$.

The two relaxation rates ($\lambda_{AF}$ and $\lambda_{tail}$) exhibit a $T$ dependence similar to that for $f_{AF}$ below $T_N$. In fact, the ratio $\lambda_{tail}/\lambda_{AF}$ is also $T$ independent below $T_N$, confirming the same origin for the two signals. Although $A_{tail}$ is only $\sim$22% of $A_0$, such $T$ dependence of $A_{tail}$ is reasonable for the “1/3 tail” signal. The smaller $A_{tail}$ is probably due to the coexistence of a spin-glass-like phase, which provides no “1/3 tail” signal. By contrast, the ratio $f_{AF}/\lambda_{AF}$, which corresponds to the inverse of the field distribution normalized to $H_{int}$, decreases with $T$ and approaches zero at $T_N$, as expected. We wish to emphasize that, since $\lambda_{AF}/\omega_{AF} \sim 1$ even at 1.8 K, the magnetic order in Sr$_2$VO$_4$ is different from a usual long-range AF order, for which $\lambda_{AF}/\omega_{AF} \ll 1$.

Such a broad field distribution is more likely to support orbital-stripe order and collinear AF spin order [8,9] rather than alternating spin-orbital order [11]. This is because, even for the single muon site in the lattice, dipole field calculations showed that there are several $H_{int}$’s in the former case, while only one well defined $H_{int}$ would be expected in the latter case.

Finally, the $\chi_m(T)$ curve obtained with $H = 10$ Oe indicates a clear increase below $T_N$, in addition to the remarkable anomaly around 105 K. The present work clearly demonstrates that the bulk magnetic transition does not occur at 105 K but at 9.2 K for Sr$_2$VO$_4$.

In order to study the change in local magnetic environments at $T_c = 105$ K, Fig. 4 shows the $T$ dependences of the fitted $\mu^+SR$ parameters obtained from WTF measurements with $H_{TF} = 30$ Oe, together with the ZF $\mu^+SR$ parameters. Here, WTF means that $H_{TF} \perp \vec{S}_m$ and $|H_{TF}| \ll |H_{int}|$. The WTF spectra were fitted by

$$A_0 P_{TF}(t) = A_{TF} \cos(\omega_{TF}t + \phi)e^{-\lambda_{TF}t} + A_M e^{-\lambda_{AF}t},$$

where $A_{TF}$ and $A_M$ are the asymmetries for the oscillatory signal due to applied WTF and the nonoscillatory relaxing signal caused by localized magnetic moments.
From the $A_{TF}(T)$ curve in Fig. 4(a), the whole volume of the sample is found to be paramagnetic above 40 K, as shown in Fig. 3(a). Although the $\lambda_{TF}(T)$ curve, which corresponds to the spin-spin relaxation rate, seems to show a small maximum around 100 K, this feature is obviously not magnetic but rather structural and/or electric in origin. The anomaly in the $\chi_m(T)$ curve at $T_c$ is thus likely to show the formation of a spin-singlet-like state, as for other vanadium oxides, e.g., $V_2O_7$ (Refs. [18,19]) and $K_2V_8O_{16}$ [20–22]. A slight structural change in $Sr_2VO_4$ (Ref. [6]) would result in a V dimerization to be caused by inhomogeneity but highly likely an intrinsic feature of $Sr_2VO_4$. Therefore, it is highly desirable to perform careful inelastic neutron scattering studies in this $T$ range. Finally, at $T_N$, $A_{TF}$ drops to zero due to the formation of magnetic order, as seen in the ZF measurements [Fig. 3(b)].

In summary, we have investigated the magnetic nature of $Sr_2VO_4$ with $\mu^+\text{SR}$ and found the formation of static long-range AF order below 8 K, although the field distribution is very broad even at 1.8 K. By contrast, the transition at $T_c = 105$ K was found to be not magnetic. This naturally leads to a question on the recent theoretical work, in which the spin-orbit coupling plays a significant role in the magnetic ground state of $Sr_2VO_4$. This is because $T_N \ll T_c$, at which orbital ordering is proposed to occur [6,10,11].
