1T-TaS$_2$ is a layered transition-metal dichalcogenide with a very rich phase diagram. At $T = 180$ K it undergoes a metal to Mott insulator transition. Mott insulators usually display antiferromagnetic ordering in the insulating phase but 1T-TaS$_2$ was never shown to order magnetically. In this paper we show that 1T-TaS$_2$ has a large paramagnetic contribution to the magnetic susceptibility but it does not show any sign of magnetic ordering or freezing down to 20 mK, as probed by muon spin relaxation, possibly indicating a quantum spin liquid ground state. Although 1T-TaS$_2$ exhibits a strong resistive behavior both in and out of plane at low temperatures we find a linear term in the heat capacity suggesting the existence of a Fermi surface, which has an anomalously strong magnetic field dependence.

DOI: 10.1103/PhysRevB.96.195131

The elusive quantum spin liquid (QSL) state has been the subject of numerous papers since Anderson suggested the resonating valence bond as the ground state of the $S = 1/2$ quantum Heisenberg antiferromagnet on a triangular lattice [1]. A QSL is an exotic state of matter with an insulating ground state that does not break the crystal symmetry. The spins are highly entangled, and quantum fluctuations prevent magnetic ordering down to absolute zero $T = 0$ K. Theoretically, it has been suggested that a QSL can support exotic spinon excitations [1–3].

The experimental search for QSL materials has been focused on $S = 1/2$ quantum spin systems on frustrated lattices with triangular motifs. Despite extensive research, very few candidates exist: the two-dimensional (2D) kagomé hebertsmithite and vesignieite [4,5]; the 2D triangular lattices $\kappa$-(BEDT-TTF)$_2$Cu$_2$(CN)$_3$, EtMe$_2$Sb[Pd(dmit)$_2$]$_2$, and YbMgGaO$_4$ [6–12]; and the three-dimensional hyperkagomé Na$_2$Ir$_3$O$_8$ [13,14].

Recently, 1T-TaS$_2$ has been suggested to have a QSL ground state [15]. 1T-TaS$_2$ has been a major subject of interest for over 40 years owing to its very rich phase diagram, arising from strong electron-electron and electron-phonon couplings [16,17]. At high temperatures ($> 550$ K) the system is metallic, and it undergoes a series of charge-density wave (CDW) transitions as the temperature is lowered. It can even become superconducting when subjected to external pressure or chemical disorder [18,19].

Despite the seemingly complicated electronic properties, 1T-TaS$_2$ has a simple crystal structure composed of weakly bound van der Waals layers; each layer contains a single sheet of tantalum (Ta) atoms, sandwiched in between two sheets of sulfur (S) atoms in an octahedral coordination. The Ta atoms within each layer form a 2D hexagonal lattice.

The basic CDW instability is formed within the Ta layers by the arrangement of 13 Ta atoms into a “star-of-David” shaped cluster, where 12 Ta atoms move slightly inwards towards the 13th central Ta atom. In the temperature range of $\sim 350$–550 K the system is in the incommensurate CDW phase. When cooled below $\sim 350$ K, the system is in the nearly commensurate state, where the CDW clusters lock in to form commensurate domains, and the domains in turn form a triangular lattice. The size of the domains becomes larger as temperature is decreased until all the domains interlock into a single coherent CDW modulation extending throughout the layer. This transition into the commensurate CDW (CCDW) phase occurs at $T_{\text{CCDW}} \sim 180$ K and is accompanied by a metal-insulator (MI) transition. The MI transition is easily visible in resistance measurements [as an abrupt jump in the resistance; see Fig. 1(a)]. Below $T_{\text{CCDW}}$, the large negative slope in resistance as a function of the temperature indicates an insulating behavior. Heating the sample reveals a hysteretic behavior expected from a first-order transition.

In the CCDW phase the unit cell is reconstructed into a rotated triangular lattice with a unit cell of size $\sqrt{3} \times \sqrt{3}$ of the original lattice. In the reconstructed lattice, every site is the center of the 13-atom star-of-David cluster. Each Ta atom has a 4+ valence and a single 5d electron, thus we have a single unpaired electron per cluster. Based on band theory the ground state should be metallic; however, interactions localize the electrons, driving the system into a Mott insulating state [20]. A Mott insulator is expected to be an antiferromagnet since when neighboring spins are oppositely aligned one can gain energy of $J = 4t^2/U$ by virtual hopping. This exchange energy, $J$, is the effective interaction between two neighbor spins. So far magnetic ordering has never been observed in 1T-TaS$_2$ [21–24].

Evidence for a QSL state is usually circumstantial and it is usually easier to rule out other possible ground states and suggest a QSL by elimination. The necessary ingredients for a QSL state are (a) a charge gap, as the material should be insulating at the ground state; (b) the existence of an odd number of unpaired spins (electrons) per unit cell; and (c) the spins do not order down to 0 K.

High-quality single crystals of 1T-TaS$_2$ were grown using standard chemical vapor transport method [25] with iodine as transport gas. The crystal structure and chemical compositions were verified using x-ray diffraction and energy-dispersive x-ray spectroscopy. No spurious phases were found; in particular, none of the other TaS$_2$ polymorphs is present in the
commensurate phase. When the temperature is lowered to below 5 K, a first-order phase transition from the nearly commensurate to the 1/3-commensurate state occurs. We find that large normalized resistance, $R/R_{300K}$, shoots up and the material is said to be in the Mott insulating state. Additional details can be found in the Supplemental Material.

Both curves exhibit the same behavior with a sharp increase in $R/R_{300K}$ at $T = 180$ K when cooled down, due to the hysteretic nature of the transition. The Curie-Weiss fit to the data yields a Curie temperature $\theta_{CW} = -2.1 \pm 0.2$ K, $C = 1.53 \pm 1.2E-6$ emu K/mol, and $\chi_0 = 4E-5 \pm 3.7E-8$ emu/mol. The Curie constant $C$, depends on the spin volume density, $n$, and the $g$ factor.

$C = \frac{ng^2S(S+1)\mu_B^2}{3k_B}$

thus from $C$ we can extract the number of spins and compare it to the number of Ta atoms in our sample. $g$ and $n$ are obtained based on inelastic neutron experiments [28]. Using this value for the effective moment in Eq. (2) we find a spin concentration of 1 spin per 2450 Ta atoms or $0.4\%$ of the expected spin density based on the Mott insulator model [20]. This concentration is too high to be the result of spurious magnetic impurities. Moreover, our value for the Curie constant is in agreement with susceptibility measurements done by other groups [22,28–30], suggesting that the Curie-like contribution is intrinsic to the 1T-TaS$_2$ crystal.

The Curie-Weiss fit to the data yields a Curie temperature $\chi = C/[(T - \theta_{CW}) + \chi_0]$. The best fit results in $\theta_{CW} = -2.1 \pm 0.2$ K, $C = 1.53 \pm 1.2E-6$ emu K/mol, and $\chi_0 = 4E-5 \pm 3.7E-8$ emu/mol. The Curie constant $C$, depends on the spin volume density, $n$, and the $g$ factor. In order to measure the $g$ factor we have performed electron-spin resonance at 9 GHz. In agreement with Ref. [22], we could not find a resonance up to a magnetic field of 1.6 T and down to a temperature of 5 K. This suggests that either the $g$ factor is smaller than 0.44 or the resonance is too broad to be observed.

Very recently, an effective moment $\mu_{eff} = 0.4\mu_B$ was reported based on inelastic neutron experiments [28]. Using this value for the effective moment in Eq. (2) we find a spin concentration of one spin per 130 Ta atoms or one spin per ten stars of David. Using a more conservative value of $g = 2.0$ we get a spin concentration of 1 spin per 2450 Ta atoms or 1 spin per 188 stars of David. We find a spin concentration of 10 to 0.5% of the expected spin density based on the Mott insulator model [20]. This concentration is too high to be the result of spurious magnetic impurities. Moreover, our value for the Curie constant is in agreement with susceptibility measurements done by other groups [22,28–30], suggesting that the Curie-like contribution is intrinsic to the 1T-TaS$_2$ crystal.

asymmetry was fitted using respectively. (c) Longitudinal field μ solid lines are the average 

The ZF asymmetry was fitted using μ mK (ZF measurements), implying the absence of frozen moments. (b) Temperature dependence of the muon spin damping rate, circles are measurement results, while the solid lines are the fit results. (a) Averaged muon polarization at 50-G transverse field at several temperatures, below and above θ_CDW. The circles are measurement results, while the solid lines are the fit results. (b) Temperature dependence of the muon spin damping rate (λ) is a useful measure for detecting magnetic ordering or spin freezing. Frozen local moments will result in an increase in λ.

We turn now to muon spin rotation (μSR) measurements and show that 1T-TaS_2 shows no sign of magnetic freezing even at temperatures as low as 20 mK. μSR is a very sensitive tool which can detect small local magnetic fields originating either from long- or short-range order, as well as spatial inhomogeneities. The temperature dependence of the muons’ polarization damping rate (λ) is a useful measure for detecting magnetic ordering or spin freezing. Frozen local moments will result in an increase in λ.

We have performed zero-field (ZF) measurements at the EMU beam-line at ISIS and weak transverse-field (TF) measurements at the LTF beam-line at PSI over a wide temperature range from 200 K down to 20 mK. The TF measurements were done using a 50-G field. We present the muon polarization measured in a weak TF for several temperatures in Fig. 2(a). As can be seen there is no change in the damping.

The temperature dependence of λ for ZF and TF is presented in Fig. 2(b). Both measurements show no temperature dependence of λ, implying the absence of local static electronic moments. The difference in the absolute values of λ between the two measurements stems from the spin-relaxation mechanism probed by each method [32].

We have also performed longitudinal-field μSR measurements, as shown in Fig. 2(c). At ZF we see a slow damping of the muon’s polarization with time, that originates from frozen nuclear moments. Upon the introduction of a 50-G longitudinal field the signal completely flattens, suggesting that static local moments in our sample are much smaller than 50 G, which is a typical value for nuclear moments. The μSR results are very clear: the ground state of 1T-TaS_2 is not an antiferromagnet.

Next we turn to our heat-capacity data. C_p/T as a function of T^2 at various magnetic fields is presented in Fig. 3. Above 2 K the main contribution to the heat capacity is from lattice vibrations as can be seen in the inset of Fig. 3, yielding a Debye temperature of θ_D = 156.3 ± 1.8 K, in accordance with former results [33]. At lower temperatures and low magnetic fields the data exhibit a clear field dependent deviation from 10 K and at three different magnetic fields. The symbols are measurement results while the solid lines are the fit results using P(t) = Aexp(−λt). There is a complete decoupling of the μ^+ spins from nuclear dipolar fields already at 50 G, suggesting all static moments are much smaller than 50 G.
a 2D dispersion we extract from the contribution of free carriers forming a Fermi surface, but susceptibility. Usually one would attribute the linear term to the temperature-independent paramagnetic part of the spin origin of this term is unclear, but it is probably connected to the field dependent linear term of model on a triangular lattice with a spacing of $\gamma$: 

$$\gamma = \frac{\gamma_0 T^2}{H^2} \left(\exp\left(\frac{\gamma_0}{T}\right) + 1\right)^2. \quad (3)$$

$\gamma(H)$ is a field dependent Sommerfeld term, usually attributed to fermionic quasiparticles. $\beta$ is the field independent Debye coefficient. The last term is the Schottky anomaly arising from a two-energy-level system with a gap $\tau(H)$ using $\alpha(H) = n(H)k_B\tau^2(H)$ with $n$ the number of two-level systems.

The result of the fit to the zero-field data gives a two-energy-level impurity density of $\gamma$ of 2000. This is comparable to the concentration of the nearly free spins we extract from the Curie-like term in the susceptibility data assuming $g \sim 2$.

The magnetic field affects the two-level system gap as well as the number of such impurities [see Supplemental Material for further details on $n(H)$ and $\tau(H)$ [26]].

The main finding from the heat-capacity measurements is the field dependent linear term $\gamma(H)$, shown in Fig. 4. The origin of this term is unclear, but it is probably connected to the temperature-independent paramagnetic part of the spin susceptibility. Usually one would attribute the linear term to the contribution of free carriers forming a Fermi surface, but this system is highly insulating at low temperatures. Assuming a 2D dispersion we extract from $\gamma(0)$ an effective mass of $\gamma$ electron masses. Using a simplified tight-binding type of model on a triangular lattice with a spacing of $\sqrt{3}a$ we estimate the bandwidth to be about 160 meV. On the other hand, the strong field dependence and the fact that $\gamma$ is reduced by a factor of 3 at 14 T is in agreement with a much smaller bandwidth of the order of 0.1 meV.

The magnetic field affects the two-level system gap as well as the Curie-like term in the susceptibility data assuming $\gamma_0 = \gamma_0(T)\tau^2(H)$ with $n$ the number of two-level systems. The second possibility is that the origin of the linear term then it is not clear if a linear term in the specific heat is expected at all. There are systems which are insulating due to disorder and have a finite $\gamma$ term up to some level of disorder [35]. In addition, we do not expect a field dependence of $\gamma$ for a one-dimensional conducting chain along the $c$ axis with such a bandwidth.

The second possibility is that the origin of the linear term is from thermally excited spinons close to their Fermi surface. In some models of QSL a gapless spectrum of excitations is expected [3,35]. This is a result of a formation of a band of spinons, the width of which should be of the order of $J$ [8,15]. A $J$ of the order of 100 meV means that below the CCDW transition at about 200 K the spins do not contribute to the Curie-like term, in agreement with the magnetic susceptibility results. A gapless QSL is expected to have a residual thermal conductivity $\kappa_0$ at $T \to 0$ K since the gapless spinons are itinerant excitations that carry entropy. A very recent paper claims that in $1T$-TaS$_2$ $\kappa_0 \sim 0$ at very low temperatures [37], raising doubts about the nature of the spin excitation. One possible explanation is that the gapless spin excitations are...
localized due to inhomogeneities and thus cannot conduct heat $^{30,37}$. The strong field dependence of $\gamma$ remains a puzzle in this scenario too.

To summarize, we studied the low-temperature phase of $1T$-TaS$_2$. We find an insulating behavior both in plane and out of plane, with a temperature dependence that seems to be activated type. From the magnetic susceptibility we conclude that most of the sample (90–99.5%) has a activated type. From the magnetic susceptibility we conclude that there is no magnetic ordering down to 20 mK. The main finding is the specific-heat linear term which implies the existence of gapless excitations in $1T$-TaS$_2$. These excitations have a bandwidth of $\sim 160$ meV. Finally, $\gamma$ changes significantly with an applied magnetic field. This field dependence remains unexplained.

We are indebted to P. A. Lee for helpful discussions and for a critical reading of the paper. We are grateful to E. Sela, M. Goldstein, B. Shapiro, D. Podolsky, and N. Lindner for helpful discussions. This paper was supported by the Israeli Science Foundation (work at the Technion under Grant No. 320/17 and work at Tel-Aviv university under Grant No. 382/17). Part of the $\mu$SR measurements were performed at the Swiss Muon Source (S$\mu$S), at the Paul Scherrer Institute in Villigen, Switzerland. Experiments at the ISIS Muon Source were supported by a beam-time allocation from the Science and Technology Facilities Council.
