Vascular plant-mediated controls on atmospheric carbon assimilation and peat carbon decomposition under climate change

Running head: Vascular plants and peat carbon cycling

Abstract

Climate change can alter peatland plant community composition by promoting the growth of vascular plants. How such vegetation change affects peatland carbon dynamics remains, however, unclear. In order to assess the effect of vegetation change on carbon uptake and release, we performed a vascular-plant removal experiment in two *Sphagnum*-dominated peatlands that represent contrasting stages of natural vegetation succession along a climatic gradient. Periodic measurements of net ecosystem CO$_2$ exchange revealed that vascular plants play a crucial role in assuring the potential for net carbon uptake, particularly with a warmer climate. The presence of vascular plants, however, also increased ecosystem respiration, and by using the seasonal variation of respired CO$_2$ radiocarbon (bomb-$_{14}$C) signature we demonstrate an enhanced heterotrophic decomposition of peat carbon due to rhizosphere priming. The observed rhizosphere priming of peat carbon decomposition was matched by more advanced humification of dissolved organic matter, which remained apparent beyond the plant growing season. Our results underline the relevance of rhizosphere priming in peatlands, especially when assessing the future carbon sink function of peatlands undergoing a shift in vegetation community composition in association with climate change.

INTRODUCTION

Peatlands are formed under climatic, hydrological and biological conditions that suppress the decomposition of plant litter, resulting in the accumulation of organic matter as peat. The imbalance between litter production and decomposition makes peatlands effective long-term sinks of atmospheric carbon (Yu, 2012). Indeed, despite a distribution limited to c. 3% of the Earth’s land surface, peatlands contain c. 30% of its soil carbon (Yu, 2012). In northern peatlands, *Sphagnum* mosses play a crucial role in peat accumulation due to the production of litter particularly resistant to microbial decomposition (Hájek *et al.*, 2011). However,
alteration of the hydrological balance (Talbot et al., 2014; Munir et al., 2015), increase in nitrogen availability (Bubier et al., 2007; Juutinen et al., 2010) and, more specifically, climate warming (Weltzin et al., 2000; Dieleman et al., 2015) can promote the growth and cover of vascular plants in peatlands. Such increase in the abundance of vascular plants can potentially reduce the productivity of Sphagnum mosses due to, for example, lower light availability (Chong et al., 2012) and increasing evapotranspiration (Hirano et al., 2016). In addition, considering that the decomposition rate of vascular plant litter is much faster than that of Sphagnum mosses (Dorrepaal, 2007), it is crucial to clarify the role of a higher vascular plant biomass, particularly with a warmer climate, with reference to the capability of the system to act as carbon sink (Breeuwer et al., 2010; Ward et al., 2013; Wang et al., 2015).

From a belowground biogeochemical perspective, the presence of vascular plants can supply soil microbes with labile carbon substrates via rhizosphere exudates, providing additional energy to invest in decomposition of old organic matter (Fontaine et al., 2007; Schmidt et al., 2011): a process known as the priming effect (Kuzyakov, 2010). Nevertheless, it is still unknown whether the priming effect in peatlands is directly linked to the abundance of vascular plants, and whether the priming effect shows any seasonal trend, particularly in relation to plant phenology. Answering these questions can help to better predict how climate warming will alter the carbon cycle of northern latitude peatlands when vascular plants become more abundant (Dieleman et al., 2015) and the length of the growing season increases (Piao et al., 2008).

To investigate the role of vascular plants in the seasonal net assimilation of atmospheric carbon and in the decomposition of peat carbon under contrasting climatic conditions, we performed a vascular plant-removal experiment in two Sphagnum-dominated peatlands that were located at different elevations and thereby naturally differed in mean annual
temperature, growing season length and vascular plant abundance (Table 1). As such, the comparison of our study sites should be interpreted as a space-for-time substitution (Blois et al., 2013), whereby the low elevation peatland represents the ecosystem state resulting from a natural response of vegetation to warmer climate compared to the upslope site (Klaus, 2007). During a full growing season, we periodically measured the net ecosystem CO$_2$ exchange (NEE), the ecosystem respiration ($R_{eco}$) and its radiocarbon signature, and the humification degree of dissolved organic matter in order to: 1) assess the role of vascular plants in assimilation of atmospheric CO$_2$ compared to Sphagnum mosses under contrasting climatic conditions; and 2) detect any temporal link between the presence of vascular plants and enhanced decomposition of peat through rhizosphere priming and the associated carbon release into both the atmosphere and pore water.

MATERIALS AND METHODS

Study sites and experimental design

We selected two Sphagnum-dominated peatlands located at 1035 m and 1885 m a.s.l. in Switzerland (Table 1, Table S1). At both sites, dominant vascular plant species were Eriophorum vaginatum, Calluna vulgaris and Vaccinium spp., whereas Sphagnum magellanicum, S. capillifolium and S. fallax were the dominant peat moss species (Gavazov et al., 2016). Peat depth was estimated to be > 1.5 m.

At each site, six paired 40x40 cm plots were selected in midsummer 2013. To study the effect of vascular plants on peat decomposition, we clipped the aboveground biomass of vascular plants in half of the plots (-V treatment) without disturbing the moss layer, and left the belowground roots to decompose until measurements commenced the following year (cf. Ward et al., 2009; Kuiper et al., 2014). We started the field measurements after one year in order to allow the decomposition of most living roots, in particular the most labile fine roots.
Due to the low rate of root decomposition in peatlands (Laiho et al., 2004; Moore et al., 2007), we are aware that root biomass did not completely decompose after one year, but the delay of one year in field measurements after biomass removal is, however, expected to have significantly reduced the belowground carbon allocation and root exudation in clipped plots. Vascular plants were left intact in paired control plots (+V treatment) so that our experimental set-up represents a paired-plot design with three replicates. Individual plots were delimited by 10 cm high quadratic stainless steel frames pushed to c. 5 cm depth in the living moss layer, which served as collars for gas flux measurements (see below). At regular intervals during 2013, all plots were trenched along the collars with a 30-cm long knife to avoid root colonisation. In the -V treatments vascular plant regrowth was regularly clipped in 2013, whereas no or very limited regrowth was observed in 2014. Because our primary aim was to study the biogeochemical role of vascular plants on carbon cycling, we decided to limit any secondary effects associated with vascular plant removal by shading the clipped plots (-V) with a UV-resistant mesh simulating the original vascular plant cover as preliminarily measured by photosynthetically active radiation (PAR) extinction underneath the canopy (60% and 30% at low and high elevation, respectively). By doing so, the presence of a mesh avoided the desiccation of peat mosses, maintained the natural PAR intensity, and avoided changes in soil microclimate. During gas exchange measurements this mesh was instead used over the chamber to maintain the natural light intensity. Ancillary measurements of soil temperature and soil water content in the clipped and control plots at both elevations confirmed the suitability of this approach (Table S2).

**Plant biomass and cover estimations**

In each peatland, total aboveground vascular plant biomass was estimated by destructively harvesting five random 25x25 cm quadrats at peak standing biomass in 2013. Vascular plant cover within the experimental plots was estimated non-destructively with the point-intercept
method. In brief, a pin was lowered over the vegetation through a 40x40 cm grid with 361 holes and the identity of the first intercepted plant was recorded. Species were attributed to one of the existing five categories: graminoids, shrubs, forbs, *Sphagnum* spp. mosses and standing litter, where the total surface cover equals 100%. Control plots (+V) as well as vascular plant removal plots (-V) had 100% *Sphagnum* cover.

**CO₂ flux measurements**

In 2014, one year after the start of the vascular plant removal treatment, a series of monthly CO₂ flux measurements were carried out during the snow-free period at each peatland starting in mid-April at 1035 m a.s.l. and in mid-June at 1885 m a.s.l. and lasting through to the end of October. CO₂ fluxes at ecosystem level were measured using a custom made transparent (95% light transmission) Plexiglas chamber (40x40 cm wide, 50 cm high) equipped with a diffusion infrared gas analyser (GMP343, Vaisala, Finland) and a humidity-temperature probe (HMP57, Vaisala, Finland). Air inside the chamber was mixed with a system of inbuilt computer fans. The chamber had a rubber seal on the bottom and a small capped hole on the top which remained open when the chamber was placed on the permanent stainless-steel collar to avoid pressurisation. Net ecosystem CO₂ exchange (NEE) measurements were done in full light or and were immediately followed by ecosystem respiration (R_{eco}) measurements for which the chamber was darkened with a non-transparent cover. All flux measurements were carried out between 10 am and 12 am local time, ensuring optimal photosynthetic conditions for both *Sphagnum* and vascular plants (Bragazza *et al.*, 2016) with vapour-pressure deficit (VPD) below 1.5 kPa and PAR intensity above the vegetation canopy between 1400 and 2100 μmol m⁻² s⁻¹. Each measurement lasted 1 minute in order to avoid excessive heat and humidity causing condensation inside the chamber. The CO₂ flux was calculated as a linear change in concentration (ppm), taking into account
ambient atmospheric pressure and gas temperature. In this study, negative NEE represents a net CO\textsubscript{2} assimilation by the plant community and the calculated gross ecosystem productivity (GEP) was derived from the difference between R\textsubscript{eco} and NEE.

**Radiocarbon analysis and age interpretation**

To determine the seasonal contribution of vascular plant-associated R\textsubscript{eco}, we sampled respired CO\textsubscript{2} for radiocarbon analysis in both the clipped and unclipped plots in July and at the end of September 2014 (Table S3). We used a passive CO\textsubscript{2} sampling method to determine the radiocarbon signature of ecosystem respiration (Garnett *et al.*, 2009). In brief, specific PVC chambers (10 cm diameter, 10 cm height) connected to a zeolite molecular sieve cartridge (MSC) were gas-tight mounted on collars of similar size pre-installed in 2013 in each plot at 7 cm depth. Prior to sample collection, the atmospheric CO\textsubscript{2} in the chamber headspace was scrubbed by pumping it at a constant rate (0.5 l min\(^{-1}\)) through a soda lime column for 10 min while monitoring the concentration. The chambers were then left in place for 10 days until, based on CO\textsubscript{2} production rates, a sufficient amount of CO\textsubscript{2} (i.e. ≥ 3 ml) was passively trapped on the MSCs by diffusion without the use of an external pump. The trapped CO\textsubscript{2} was thermally recovered (425 °C) while purging with high-purity nitrogen gas, converted to graphite by Fe/Zn reduction and analysed by acceleration mass spectrometry (AMS) at the NERC Radiocarbon Facility in Scotland, UK (Garnett & Murray, 2013). Subsamples of CO\textsubscript{2} were measured on a dual inlet stable isotope mass spectrometer (Thermo Fisher Delta V) to determine their δ\textsubscript{13}C signature.

In addition, we evaluated the apparent carbon accumulation rate at the two peatlands by splitting one 20-cm long peat core from each site into 5 cm segments. From these segments, vascular plant remnants were removed, after which the carbon content, peat density and peat age were determined (Table S4). After the combustion of these samples in a high-pressure
bomb in the presence of oxygen, CO$_2$ was converted to graphite as above. The peat age was estimated by matching the $^{14}$C content with a known record (Levin et al., 2013) of atmospheric $^{14}$CO$_2$ in order to estimate the date of carbon fixation (Goodsite et al., 2001) according to Cali-Bomb program for post-bomb $^{14}$C samples (see Reimer et al., 2004).

Following convention (Stuiver & Polach, 1977), all radiocarbon data were corrected for mass dependent fractionation by normalising to $\delta^{13}$CVPDB values of -25‰ using the measured $\delta^{13}$C values, and reported as %Modern with reference to the Oxalic Acid international radiocarbon standard. These data (Table S3) were not subjected to further corrections for atmospheric air contamination during chamber enclosure (Czimczik et al., 2006; Natali et al., 2011; Hartley et al., 2012; Hicks Pries et al., 2013) as the fraction of atmospheric CO$_2$ in the recovered samples proved low and subsequent $^{14}$C corrections remained within the AMS measurement uncertainty (± 0.5 %Modern).

To distinguish between vascular plant-derived respiration and respiration from peat induced by the presence of vascular plants (i.e. the rhizosphere priming effect), we made a common-practice assumption that vascular plants respire contemporary carbon with a $^{14}$C signature identical to the current atmosphere (Subke et al., 2011; Hartley et al., 2012), whereas subsurface peat respires older carbon (Hardie et al., 2007), which has become very likely incorporated during the post-1963 bomb-$^{14}$C spike at our studied sites (Table S3). Experimental evidence from peatlands dominated by herbaceous vegetation supports this assumption for vascular plant shoots (Czimczik et al., 2006; Hicks Pries et al., 2013), and further indicates only a small contribution of carbon fixed in the preceding year (i.e. up to 0.7 %Modern enrichment) for roots (Hicks Pries et al., 2013, 2015). A sensitivity analysis confirmed that our conclusions were robust regardless of whether we used current year atmospheric $^{14}$C values or those from the preceding year. We used data from the nearby Jungfraujoch (53°20′ N, 9°54′ W, 3580 m a.s.l.) long-term atmospheric $^{14}$C monitoring.
station (Levin et al., 2013) to calculate a mean seasonal value (June, July, August and September) for the expected vascular plant-derived $^{14}\text{C}$ signature for the 2014 growing season, which was 102.91 %Modern $^{14}\text{C}$. Elevation differences between the study sites and the $^{14}\text{C}$ monitoring station at the Jungfraujoch are expected not to affect the $^{14}\text{C}$ values due to atmospheric mixing (Levin et al., 2008). To this value, we compared the $^{14}\text{C}$ signature of the vascular plant-associated respiration ($D_{V\_plant\_associated}$) in our experiment. Following Hardie et al. (2009), the latter was calculated using a two pool mixing model:

$$D_{V\_plant\_associated} = \frac{(D_{+V} R_{+V} - D_{-V} R_{-V})}{(R_{+V} - R_{-V})}$$

where $R$ represents the rate of ecosystem respiration measured on the day of chamber enclosure and $D$ its $^{14}\text{C}$ signature in plots with (+V) and without (-V) vascular plants. The vascular plant-associated respiration in our experiment consisted of vascular plant-derived respiration and, potentially, of vascular plant-induced peat respiration. A significant deviation in the calculated $^{14}\text{C}$ signature of vascular plant-associated respiration from that of the expected vascular plant-derived $^{14}\text{C}$ signature (ambient atmosphere) was interpreted as an extra source of heterotrophic peat respiration in the presence of vascular plants, i.e. the rhizosphere priming effect.

**Pore-water sampling and chemical analyses**

Representative pore-water samples were collected monthly during May-October 2014 from four permanent microporous (0.20 $\mu$m) rhizons (Rhizosphere Research Products, The Netherlands) installed in each plot at the rooting depth, i.e. from 5 to 15 cm below the surface. Concentration of ammonium ($\text{NH}_4^+$) and nitrate ($\text{NO}_3^-$) were obtained colorimetrically on a continuous-flow autoanalyser (SEAL Analytical, Germany), whereas total nitrogen (TN) and dissolved organic carbon (DOC) were determined by combustion on a Shimadzu analyser (TOC-V CPHCTNM-1). In order to characterise the quality of dissolved
organic matter (DOM) and its level of humification, lyophilised subsamples were analysed on a Frontier FT–NIR/MIR Spectrometer (PerkinElmer, USA). The recorded spectra (4000 to 400 cm\(^{-1}\)) of diamond attenuated total reflectance provide information on the DOM functional groups aliphatics (2943 cm\(^{-1}\) region), carboxylic acids and aromatic esters (1720 cm\(^{-1}\) region), aromatics (1630 cm\(^{-1}\) region), lignins (1510 cm\(^{-1}\) region), phenols (1420 cm\(^{-1}\) region), and polysaccharides (1090 cm\(^{-1}\) region) (Niemeyer et al., 1992; Biester et al., 2014). During peat decomposition, substances enriched in carboxylic, aromatic and phenolic groups accumulate with respect to labile polysaccharides, thereby increasing the specific ratios between these moieties (Biester et al., 2014). Commonly referred to as humification indices, the ratios 2943/1090, 1720/1090, 1630/1090, 1510/1090, 1420/1090 can be used as an indication of the level of organic matter decomposition (Broder et al., 2012; Hodgkins et al., 2014).

**Statistical analysis**

Data on seasonal CO\(_2\) fluxes and pore-water chemistry were analysed as a paired-plot design for the effect of vascular plant removal in each peatland. The hierarchical structure was coded in R3.3 (R Core Team, 2016) as a linear mixed-effects model using the *nlme* package (Pinheiro et al., 2016), accounting for the spatial proximity of +V (control) and -V (clipped) pairs and the repeated measurements in individual plots. Assumptions of normality and homoscedasticity of the residuals in all final models were verified visually using diagnostic plots, and the simplest models were retained by pooling non-significant interactions with the error term. Comparisons between the radiocarbon signature of the atmosphere and the estimated vascular plant-associated CO\(_2\) were done in R using One Sample t-tests for each site and sampling date.
RESULTS

The main hydrological (water-table depth) and hydro-chemical (water pH and electrical conductivity) parameters were comparable between the two peatlands and overall typical of ombrotrophic peatlands, i.e. rain-fed bogs (Table 1). The main differences between the two sites were related to climatic conditions and abundance of vascular plants, with characteristically higher air temperature, lower precipitation and higher shrub biomass at low elevation (Table 1, Table S1). Because the cover of peat mosses at plot level did not differ between the two sites (100% at both sites), the study sites can be regarded as a natural climate change experiment where the natural climatic gradient resulted in similar plant community composition, but with different abundance of vascular plants in response to soil microclimate (Table 1, Table S2).

Overall, the net ecosystem exchange of atmospheric carbon (i.e., NEE) was weaker (i.e. smaller sink capacity) at low elevation with warmer climatic conditions \((F_{1,4} = 15.5, P = 0.017)\) despite the larger vascular plant biomass (Fig. 1a). Nevertheless, in both peatlands the presence of vascular plants (+V treatment) increased \((F_{1,35} = 19.4, P < 0.001)\) the net CO\(_2\) assimilation by c. 50% compared to the treatment with Sphagnum mosses alone (-V treatment) (Fig. 1a). Furthermore, at low elevation the absence of vascular plants prevented a net assimilation of atmospheric carbon during most of the growing season (Fig. 1a).

During the peak of the growing season, vascular plants contributed to about 50% to gross photosynthesis at both elevations (Fig. 1b) as indicated by the two-fold reduction of potential gross ecosystem productivity (GEP) upon vascular plant removal \((F_{1,35} = 50.2, P < 0.001)\). Although vascular plant biomass was significantly larger at low elevation (Table 1), the GEP was similar at both sites in the presence of vascular plants (+V). In the absence of vascular plants (-V), GEP of Sphagnum mosses was also comparable between the two sites (Fig. 1b).
Overall, ecosystem respiration ($R_{\text{eco}}$) was slightly larger at low elevation as compared to high elevation site ($F_{1,4} = 6.4, P = 0.064$) and at both sites the presence of vascular plants increased $R_{\text{eco}}$ ($F_{1,35} = 46.9, P < 0.001$) (Fig. 1c). By taking into account the CO$_2$ flux and the corresponding $^{14}$C signature in plots with and without vascular plants, the two-pool mixing model revealed that late in the growing season the vascular plant-associated respiration was more enriched in bomb-$^{14}$C than would be expected from autotrophic contributions alone at both low ($t_{1,2} = 8.8, P = 0.006$) and high ($t_{1,2} = 2.7, P = 0.053$) elevation (Fig. 2). An enrichment in bomb-$^{14}$C likely occurred also during the peak of the growing season in July (Fig. 2); however, it was masked by larger variability at both low ($t_{1,2} = 1.4, P = 0.153$) and high elevation ($t_{1,2} = 1.9, P = 0.096$).

On the basis of pore-water chemistry, the peatland at low elevation was characterized by a c. 30% greater concentration of dissolved organic carbon (DOC) (Table 1). Furthermore, the FT-IR spectroscopy demonstrated that the presence of vascular plants (+V) was associated with a consistently higher humification of dissolved organic matter in both peatlands. This was indicated by higher concentrations of aliphatic, carboxylic, aromatic, lignin, and phenolic compounds in proportion to more labile polysaccharides (Fig. 3).

**DISCUSSION**

Our net ecosystem exchange (NEE) measurements under optimal conditions and during the peak of diurnal photosynthetic activity provide an objective assessment of the potential contribution of vascular plants and *Sphagnum* mosses to the exchange of atmospheric CO$_2$ in the two contrasting peatlands (Bahn *et al.*, 2009; Bragazza *et al.*, 2016). The NEE results demonstrate that the presence of vascular plants is crucial to maintain high levels of net CO$_2$ assimilation in the two peatlands during the growing season (Laine *et al.*, 2012; Ward *et al.*, 2013; Kuiper *et al.*, 2014). *Sphagnum* mosses alone were much less efficient in offsetting...
ecosystem respiratory CO$_2$ losses under warmer conditions. Concurrently, gross ecosystem productivity (GEP) in both peatlands was much higher in the presence of vascular plants, in accordance with the higher photosynthetic efficiency of vascular plants compared to mosses (Ward et al., 2009; Armstrong et al., 2015). Despite the larger aboveground plant biomass at lower elevation, GEP was not significantly different between the two peatlands, a result that can be at least partly explained by a larger abundance of shrubs with a greater portion of ligneous, non-photosynthetic tissues at low elevation (Table 1; Fig. S1) (Bubier et al., 2003; Leppälä et al., 2008; Juutinen et al., 2010). On the basis of our field measurements, Sphagnum mosses in the two peatlands contributed equally to GEP per surface area, indicating that under suitable conditions of temperature and moisture the photosynthetic potential was the same at both elevations even if the annual productivity can be different (Bragazza et al., 2013). Indeed, albeit a longer growing season (Fig. 1), both vascular plants and Sphagnum mosses are likely to experience more limiting photosynthetic conditions at lower elevation due to higher VPD values (Table 1).

The overall greater R$_{eco}$ in the presence of vascular plants, particularly at low elevation, is likely due to a higher contribution of autotrophic respiration, in line with: the larger vascular plant biomass (Ward et al., 2013; Kuiper et al., 2014; Hicks Pries et al., 2015), the corresponding larger biomass of decomposing roots (Murphy et al., 2009), as well as to an enhancement of heterotrophic respiration, i.e. a boosting of microbial metabolism. The latter can be directly stimulated by the improved soil physical conditions due to warmer climate (Updegraff et al., 2001; Dorrrepaal et al., 2009; Conant et al., 2011; Philben et al., 2014) or indirectly promoted by vascular plants through the rhizosphere priming. The two-pool mixing model, taking into account the CO$_2$ efflux and the corresponding $^{14}$C signature in plots with and without vascular plants at each peatland, shows a consistent enrichment of vascular plant-associated respiration with older carbon, a result that clearly indicates a stimulation of
heterotrophic peat decomposition through the rhizosphere priming effect (Hardie et al., 2009; Basiliko et al., 2012; Walker et al., 2016). Although we cannot exclude a contribution of residual decomposing roots to the priming (even after one year of decomposition), if this should take place in the clipped plots it means that the differences in the $^{14}$C enrichment with the control plots would be still larger in total absence of roots in the peat.

A sustained expression of the rhizosphere priming towards the end of the growing season is intriguing because it indicates that the priming can still be active beyond the plant growing season, i.e. when soil and air temperatures as well as GEP already decline (Fig. 1, Table S2). We interpret this apparent temporal asynchrony between aboveground plant productivity and belowground microbial decomposition as result of: i) the low thermal diffusivity of peat that maintained favourable soil temperatures later into the growing season (Table S2), ii) the preferential allocation of carbon resources by vascular plants to their roots well beyond their aboveground senescence (Abramoff & Finzi, 2015; Blume-Werry et al., 2016), and iii) the leaching from fresh leaf litter (Singh et al., 2014) providing soil microbes with labile carbon substrates to access older organic matter (Qiao et al., 2014).

On the basis of FT-IR spectroscopy, at both studied sites there was a higher humification degree of dissolved organic matter in plots with intact vascular plants (Fig. 3), a result that seems to reflect an enhanced microbial metabolism (Glatzel et al., 2003; Höll et al., 2009; Ward et al., 2013; Lou et al., 2014; Dieleman et al., 2016). The removal of vascular plants is indeed expected to reduce the availability of more labile, root-mediated carbon (Gogo et al., 2011) that is used by microbes for synthesising extracellular enzymes (Robroek et al., 2016). Additionally, we observe that warmer climatic conditions and larger vascular plant biomass are ultimately associated with a larger release of dissolved organic carbon (DOC) in the peat soil at low elevation (Table 1). This latter result points to the synergetic role of climate and
vegetation in increasing the production and release of DOC from peatlands (Neff & Hooper, 2002; Frey & Smith, 2005; Ward et al., 2013; Kane et al., 2014).

On the basis of the \(^{14}\)C signature in the subsurface peat (Table 1), the estimated age of top 20 cm peat, particularly for the low elevation site, was in line with other studies (see e.g. Shotyk et al., 1997) suggesting a relatively recent peat accumulation, i.e. primarily after the bomb- \(^{14}\)C peak of 1963. We conclude that the carbon released by the priming effect was only a few decades old (< 20 years) and stored above the mean water-table depth (Table 1). This observation highlights the importance of water table in protecting peat from microbial decomposition (Ise et al., 2008), but also indicates the potential vulnerability of peat carbon if hydrological feedbacks to climate change increase soil oxygenation (Waddington et al., 2015) and, consequently, promote the spreading of vascular plants (Dieleman et al., 2015; Potvin et al., 2015). The apparent rate of carbon accumulation in the peat layers above the mean-water table depth approximated c. 90 g C m\(^{-2}\) y\(^{-1}\) for the low elevation site and c. 154 g C m\(^{-2}\) y\(^{-1}\) for the high elevation site over a reference period of 26-30 years for both sites, a result suggesting a lower carbon sink capacity of peatlands at the lower end of their altitudinal distribution (Millar et al., 2017). The effective annual contribution of the rhizosphere priming to the observed difference in carbon accumulation rate in relation to the dominant vascular plant functional types and their symbiotic microorganisms remains an open question that deserves further attention (Gavazov et al., 2016; Walker et al., 2016; Sulman et al., 2017).

Our \(\text{CO}_2\) exchange measurements, whilst covering only a single growing season, show that the presence of vascular plants is crucial to sustain high potential levels of net atmospheric carbon assimilation in peatlands, particularly with warmer climate. Differently, \textit{Sphagnum} mosses alone could not keep pace with the observed higher ecosystem respiratory C-losses with warmer climate. A sustained temporal expression of the rhizosphere priming

effect, although deserving further investigation (Luo et al., 2016), suggests that the decomposition of older peat can be promoted even beyond the plant growing season, so affecting the humification of peat and loss of C in both gaseous and dissolved form. We argue that to accurately predict the future capacity of peatlands to act as atmospheric carbon sinks the synergetic interactions among vegetation dynamics, plant phenology and soil microbes must be taken into account, particularly if the rhizosphere priming effect can be further stimulated in warmer soils (Zhu & Cheng, 2011), thereby exerting a positive feedback to carbon emissions from organic rich soils.

ACKNOWLEDGEMENTS
We thank Lucas Wettstein and Adrian Pulgarin for field assistance and to Vincent Jassey and Laurent Jeanneau for laboratory assistance. Thanks are also due to Ingeborg Levin and Samuel Hammer for providing data on $^{14}$C signature of atmospheric CO$_2$. The Service des Forêts, de la Faune et de la Nature (Canton de Vaud) and the Service de la promotion de la nature – Office de l'agriculture et de la nature (Canton de Berne) are acknowledged for giving the permission to access the studied peatlands. This work was supported by the Swiss National Science Foundation grant number: 205320_144024 to L.B.

TABLE 1 Geographical location, climatic conditions for the year 2014 and the average for the period 2005-2013 (in brackets), cumulative hours of vapour-pressure deficit (VPD) and water-table depth during plant growing season 2014, vascular plant biomass and surface cover (%), pore-water chemistry, and estimated age of surface peat (with corresponding $^{14}$C signature) at the two study sites. Aboveground plant biomass is the mean of 5 replicates for each site. Water table depth is the seasonal mean of continuous measurements collected in one representative piezometer during the plant growing season at each site. Plant cover estimates are mean ($\pm$ 1 SE) of 3 replicates for each site. Pore-water chemistry is the seasonal mean ($\pm$ 1 SE) of 3 replicates for each site as measured in the control plots where vascular plants were not clipped (+V treatment). Different superscripts indicate significant differences between the peatlands ($P < 0.05$). The age of the peat was calculated from a reference dataset of atmospheric $^{14}$C measurements carried out at the Jungfraujoch station and refers to years before 2014.

FIGURE CAPTIONS

**Fig. 1** Seasonal dynamics of ecosystem CO₂ fluxes in relation to the presence or absence of vascular plants in two peatlands at different elevations. (a) Net ecosystem exchange (NEE), (b) Gross ecosystem productivity (GEP), (c) Ecosystem respiration (R_{eco}). The two peatlands were located at low (1035 m a.s.l.) and high elevation (1885 m a.s.l.) and two treatments were applied, i.e. mosses plus vascular plants present (+V, controls) or removal of vascular plants by clipping (-V, *Sphagnum* mosses alone). Panels on the left show the seasonal dynamics of mean values (± 1 SE, n = 3), whereas those on the right show the overall seasonal means (± 1 SE, n = 3). Asterisks indicate significant differences of mean CO₂ fluxes between treatments at each site and between elevations (*' = P < 0.1; * = P < 0.05; *** = P < 0.001). Negative values of NEE indicate a net assimilation of atmospheric CO₂.

**Fig. 2** ¹⁴C content of ecosystem respired CO₂ associated with the presence of vascular plants in two peatlands at low and high elevations (1035 and 1885 m a.s.l., respectively) at peak biomass (July) and late in the growing season (end of September). (n = 3) of respired ¹⁴C-CO₂ associated with the presence of vascular plants (DV_plant_associated). Dotted line indicates the mean atmospheric ¹⁴C-CO₂ signature (102.91 %Modern) as measured in June, July, August and September 2014 at the Jungfraujoch atmospheric research station. Numbers beneath the dotted line are P-values from t-tests for differences of each date and elevation to this reference line. Significant differences (P < 0.05) are interpreted as a signal of plant-induced heterotrophic respiration of peat carbon through the rhizosphere priming effect.

**Fig. 3** Mean seasonal values (± 1 SE, n = 3) of humification indices of dissolved organic matter based on FT-IR spectra. Pore-water samples were collected monthly from May through October 2014 in the two peatlands at low and high elevations (1035 and 1885 m a.s.l., respectively) in relation to the presence (+V) or absence (-V) of vascular plants. The selected functional groups are: aliphatics (2943 cm⁻¹ region), carboxylic acids and aromatic esters (1720 cm⁻¹ region), aromatics (1630 cm⁻¹ region), lignins (1510 cm⁻¹ region), phenols (1420 cm⁻¹ region) and they are expressed as a ratio to polysaccharides (1090 cm⁻¹ region). Significant differences between treatments are indicated with asterisks (*' = P < 0.1, * = P < 0.05, ** = P < 0.01; *** = P < 0.001), whereas no significant differences were observed between the two sites.
