Keywords: climate change, ITEX, open-top chambers, phenology, tundra
Abstract

Advancing phenology is one of the most visible effects of climate change on plant communities, and has been especially pronounced in temperature-limited tundra ecosystems. However, phenological responses have been shown to differ greatly between species, with some species shifting phenology more than others. We analyzed a database of 42,689 tundra plant phenological observations to show that warmer temperatures are leading to a contraction of community-level flowering seasons in tundra ecosystems due to a greater advancement in flowering times of late-flowering species than of early-flowering species. Shorter flowering seasons with a changing climate have the potential to alter trophic interactions in tundra ecosystems. Interestingly, these findings differ from those of warmer ecosystems, where early flowering species have been found to be more sensitive to temperature change, suggesting that community-level phenological responses to warming can vary greatly between biomes.

Main

Warmer temperatures associated with climate change have advanced the phenology of organisms around the world 1–3, and both temperature increases and phenological changes have been especially pronounced in temperature-limited tundra ecosystems 4–7. Tundra ecosystems encompass cold regions above latitudinal treeline (Arctic tundra) or altitudinal treeline (alpine tundra). Remote sensing studies indicate broad patterns of changing seasonality of vegetation productivity at high latitudes over time in relation to climate warming 8–10, however, phenological responses to warmer temperatures have been shown to differ greatly among species and locations, with some species shifting dates of flowering and flower senescence more than others 11–15. Studies from temperate ecosystems have found that early-flowering species often advance phenological events more in response to warmer temperatures than later-flowering species 16,17–19, however, to date, the relationship between
flowering time and phenological sensitivity has not been tested across high-altitude tundra ecosystems.

Evidence suggests that across northern tundra ecosystems, phenology of plants from colder sites at higher latitudes changes more with warmer temperatures than phenology of plants from warmer, more southern latitudes \(^7,15,20\). However, within tundra plant communities, phenological responses to warming are often species-specific, with no clear responses of specific functional groups \(^21-27,3\) or phylogenetic relationships \(^28\). A better understanding of the drivers of variation in phenological sensitivity will help determine how species and plant communities will respond to climate change in the future \(^23,29,3\), as well as contribute to our understanding of the adaptive nature of species-specific phenological responses to climate change.

The timing of life history events, such as flowering, is of critical importance in harsh tundra ecosystems, and the fitness consequences of different phenological responses to climatic drivers can be substantial \(^30,31\). Plants that track snowmelt dates and not temperature (or thermal sums) may risk exposure to freezing events that can damage flowers and reduce seed production during early snowmelt years \(^32-35\), whereas plants that flower too late risk not being able to fully develop seeds before the end of the growing season, and may be at a competitive disadvantage to plants that do respond \(^22,36\).

There are a diversity of life history strategies among species in tundra plant communities, even within the short growing seasons experienced at high latitudes and altitudes \(^21,22,37\). These various strategies could influence the species-specific responses of plants to warmer temperatures \(^37,38,12\). The relative flowering time of a species compared to other species in the plant community (hereafter its “phenological niche”) could help explain the variation in phenological responses among species in tundra ecosystems. The existence of different phenological niches could promote species coexistence in many ecosystems \(^39-41\), as phenological niches can strongly influence competitive and trophic interactions \(^42\). Differential
shifts in the phenological niche could lead to trophic mismatches in tundra ecosystems, altering food webs and influencing the abundance of pollinators or herbivores \(^{43-45,12}\).

Classifying organisms using phenological niches could thus be a useful way to predict how species will respond to changes in environmental conditions in the future \(^{38}\).

Measuring the relative importance of different environmental cues for Arctic and alpine species, such as temperature and snowmelt date, will help determine how species will respond as the climate warms \(^{23,29}\). Although temperature influences the date of snowmelt, snowmelt can be decoupled from temperature because snowmelt is also influenced by the amount and quality of precipitation over winter and spring \(^{13}\). The phenology of early-flowering plant species may be influenced more by photoperiod or the timing of snowmelt, whereas the phenology of late-flowering species is probably more dependent on thermal heat sums accumulated over the growing season \(^{22,46}\). If early-flowering tundra species are less responsive to changes in summer temperature than late-flowering ones, then increases in summer temperature will likely accelerate the flowering phenology of late-flowering species more than early-flowering ones. Additionally, if temperatures towards the end of the growing season are rising more rapidly than temperatures at the beginning of the year, then flowering phenology of late-flowering species will advance more than that of early-flowering species \(^{14,15}\). In both cases, a more rapid advance of late- than early-flowering species would result in a contraction of the community-level flowering season (Fig. 1, \(^{12}\), which could substantially change competitive and trophic interactions \(^{47,44,12,31}\). In particular, shorter flowering seasons could also strongly limit resource availability for pollinators, especially if the phenology of pollinator species are responding to different drivers than plant communities \(^{12,48}\).

In this data synthesis, we test how the temperature sensitivity of flowering relates to the phenological niches of tundra species using flowering observations of a total of 253 species, 23 sites, and up to 20 years from Arctic and alpine ecosystems around the world, both from long-term monitoring plots and warming experiments (Fig. 2). With this global dataset,
we tested three main hypotheses: 1) flowering phenology of late-flowering tundra species is more sensitive to warmer summer temperatures than flowering phenology of early-flowering species. We tested this hypothesis with both observational and experimental data, and hypothesized that: 1a) results would be similar for both observational and experimental data; that is, late-flowering species would be more sensitive to natural and experimental warming. 2) If late-flowering species are flowering earlier, but early-flowering species are not, then the community-level flowering seasons will be shorter in warmer years, and thus, 3) as average summer temperatures at tundra sites have warmed in the recent past, the duration of community-level flowering seasons have decreased over this time period. We examined how the phenological niche of a species influenced the sensitivity of first flowering dates (FFDs) and flower senescence dates (LFDs) to summer temperature indices, snowmelt date, and experimental warming. To test for a contraction of community-level flowering seasons with warmer summers and over time, we compared the community flowering season length to mean June-July temperatures and year for six sites with observations of four or more species over 10 or more years.

**Results**

First flowering dates (FFDs) of late-flowering species were more temperature sensitive than early-flowering species (i.e., FFDs of late-flowering species advanced more per °C increase in summer temperature, and in response to experimental warming, than early-flowering species, Figs. 3A and 4A, Supplementary Fig. 1, Supplementary Table 4). Results of analyses using June temperature for all species, or the average daily temperature from snowmelt through the average flowering date, also indicated a significant influence of phenological niche on temperature sensitivity of flowering (Figs. 3B and 3C, Supplementary Table 4). However, the phenological niche of a species did not influence the sensitivity of FFDs to snowmelt timing (Fig. 3D, Supplementary Table 4). Overall, species from sites with
colder summer temperatures had greater temperature sensitivity of FFDs (Supplementary Table 4). Analyses from warming experiments yielded similar results, with greater differences in FFDs between experimentally warmed and control plots for late-flowering species than for early-flowering species (Fig. 4A). There was no influence of phenological niche on the temperature sensitivity of flower senescence dates (LFDs) in either long-term monitoring plots or warming experiments (Supplementary Table 5 and Fig. 4B).

The community-level flowering seasons across the six sites with 10 or more years of data were 3.96 days shorter per 1 °C warmer June-July temperature (95% CI = -7.31, -0.79, Fig. 5A, Supplementary Table 5). The length of the flowering season was estimated as the duration between the average FFD of the earliest and average LFD of the latest flowering species per site in each year. Community-level flowering seasons became shorter over time in all six sites, but the change was significant only at Alexandra Fiord, Daring, and Zackenberg. Across all sites, flowering season length shortened by 0.43 days per year, but the credible interval on this parameter overlapped zero (95% CIs = -0.87, 0.06, Fig. 5B). Annual June-July temperatures

**Discussion**

Our results reveal an overall shortening of community-level flowering seasons with summer warming across the tundra biome. We additionally found evidence of a contraction of the community-level flowering season over time at a subset of sites. In both cases, the shortening of the flowering season was due to greater temperature sensitivity of flowering of late-flowering than early-flowering species. On average, the temperature sensitivity of first flowering dates was greater for tundra species that flowered later in the growing season compared to those that flowered earlier. This pattern was evident both in long-term monitoring plots over time and in warming experiments. Additionally, observations from long-term monitoring plots indicated that, on average, plants at colder sites were more
phenologically sensitive, consistent with results from Prevéy et al. (2018) using a largely overlapping dataset, and that late-flowering plant species at the coldest tundra sites exhibited the highest phenological sensitivities in the dataset. Our analyses of long-term monitoring and experimental warming data indicate that late-flowering tundra species may alter their flowering phenology more than early-flowering ones in a warmer world, resulting in a shortening of community-level flowering seasons at sites across the tundra biome.

The finding of greater temperature sensitivity of late-flowering species differs from results of many studies conducted at lower latitudes and altitudes\(^{6,49,18,19}\). Studies from warmer biomes found that early-flowering species often advance phenological events more in response to warmer temperatures than late-flowering species\(^{16,1,17–19,50,51}\). Mid- and late-season moisture limitation probably plays a greater role in structuring the phenology of plants in warmer ecosystems\(^{52}\). However, in cold tundra ecosystems with relatively short summers, moisture limitation may not be as important a phenological driver as in warmer, drier ecosystems\(^{53}\). Additionally, selection might be stronger at the start of the growing season under the harsher climate conditions experienced by early flowering plants in tundra sites relative to more temperature biomes\(^{46}\).

Our finding of a contraction of the flowering season with warmer temperatures also differs from studies in other ecosystems. Some studies have found a divergence of flowering dates of early- versus late-flowering species with warming in temperate grasslands\(^{49}\), montane and subalpine meadows\(^{54,55}\), and deserts\(^{53}\), with less overlap in the flowering times of species\(^{49}\), and a mid-season depression in flower abundance\(^{54,55}\). Individual studies conducted in temperate ecosystems and global meta-analyses of phenology experiments and long-term monitoring projects have concluded that early-flowering species are more responsive to climate warming\(^{18,6,51}\). However, our results show that Arctic and alpine plants exhibit the opposite pattern, suggesting that community-level phenological responses to warming can vary greatly among biomes\(^{19,56}\).
For the six Arctic sites with over ten years of observations, we documented a contraction of the flowering season with warmer temperatures, and a trend toward shorter flowering seasons over time, although this pattern was not significant at all sites. A contraction of the flowering season is in agreement with previous single-site studies in arctic ecosystems \(^5\),\(^{12,48}\). Shorter flowering seasons could lead to possible phenological mismatches if late-season pollinators or herbivores are not following the same cues as late-season plant species \(^48\),\(^{57}\). Additionally, less dispersion among the flowering times of species in a community may increase competition for pollinators \(^58\) or, alternatively, increase exposure to more pollinators because plant species are all flowering at similar times \(^59\). However, it is important to note that we did not directly measure how the abundance of plant species, or the abundance of open flowers, changed with temperature or over time. The timing of peak flowering may shift less than the timing of first flowering dates \(^55\), thus changes in coverage and abundance of flowers over the season may exhibit different patterns than changes in the overall length of the flowering season \(^60\).

Increased temperature sensitivity of flowering may be advantageous if it allows plants to track ideal temperature conditions for growth and reproduction \(^61,30\). Our results suggest that late-flowering species that track temperature more than snowmelt date or photoperiod may be more able to optimize the timing of flowering and could have an advantage as temperature increases or becomes more variable \(^62\). Phenological plasticity may also be indicative of plasticity of other plant traits, so plant species that can shift phenology to changing conditions may be better able to adjust to climate change over time. To date, there have been few studies comparing phenological traits to other plant traits and changes in plant abundance (but see \(^30,61\)). However, as the amount of phenological data available for tundra plant species accumulates, the next logical step will be linking phenological measurements to performance measurements to aid predictions of vegetation change in tundra ecosystems in the future \(^64\).
Phenological responses are one of the most easily observable effects of climate change on plant communities, but identifying the underlying mechanisms driving phenological responses to warming is crucial to accurately estimating food-web dynamics and plant-pollinator interactions. Our data synthesis demonstrates an agreement between long-term and experimental data to identify how plants respond to warmer temperatures. In temperature-limited tundra ecosystems, late-flowering species advance flowering more in warmer years, and this can lead to a contraction of the flowering season of the entire plant community.

Additionally, these changes are most pronounced at the coldest tundra sites where temperature increases have been greatest. Thus, our study demonstrates that the phenological niches of plant species can be useful predictors of how the flowering of tundra species will respond to warmer temperatures, and can aid predictions of plant and ecosystem responses to climate change in the future.

**Methods**

**Compilation of the flowering phenology database**

We compiled a database of flowering phenology observations from a total of 253 species at 23 sites in Arctic and alpine ecosystems from both long-term monitoring plots and warming experiments (Supplementary Table 1, Fig. 2). Portions of the dataset were analyzed and reported in Oberbauer et al. (2013) and Prevéy et al. (2017), however, two additional monitoring sites and 10 additional warming experiments are included in this analysis (Supplementary Table 1). Each site collected phenological observations following a standardized protocol that was originally developed for the International Tundra Experiment (ITEX) network. Following the ITEX protocol, observers recorded the phenological status of plants one to three times per week over the snow-free season, and specifically recorded the first flowering date (FFD) and last flowering date (LFD) of each species per individual or plot. The FFD was defined as the date when the first flower was open, the first
pollen was visible, or the first anthers were exposed. The LFD was defined as the date when
the withering of anthers, first petal drop, or last petal drop was observed. However, both FFD
and LFD were recorded consistently at each site over time. We include data only from long-
term monitoring plots that had three or more years of flowering phenology observations per
species per plot.

Effects of species phenological niches on the sensitivity of flowering

We calculated the phenological niche of a species at each site as the average first
flowering date of the species at each site across all years of measurements\(^5\) (Supplementary
Table 2). We examined the relationship between phenological niche and temperature
(expressed in several ways) and snowmelt dates at long-term monitoring plots. Temperature
was expressed as the mean monthly temperature until flowering, mean June temperature, or
the mean daily temperature between snowmelt and flowering. Flowering dates for the
Southern hemisphere alpine site were adjusted by 210 days to match that of the Northern
hemisphere growing season, and to assist with model convergence in analyses. We specified
mean monthly temperature until flowering separately for each species and site as the average
monthly air-temperature from June through the average month of flowering, except for 29 site
by species combinations where species flowered in May, for which we used average May
temperature (Supplementary Table 2). For example, if the phenological niche of a species was
June 30\(^{th}\), then mean June temperature was used as the summer temperature variable for that
species. However, if the phenological niche was July 15\(^{th}\), then average June-July temperature
was used (Supplementary Table 2). To test the influence of the temperature windows on the
results we obtained, we also performed the analyses with June temperature as the predictor
variable for all sites and species, because preliminary analysis showed that June temperature
was the strongest predictor of flowering across all species and sites (Supplementary Table 2).
We used average monthly temperatures because they were available for all sites in the
analyses; thus allowing us to incorporate the largest set of phenological data available. We recognize that using monthly mean temperatures may bias results, as sensitivity of flowering time for species flowering in the early parts of months are obviously not affected by temperatures experienced after they flower. Thus, for the subset of 12 sites with both daily temperature data and snowmelt dates available we calculated the mean daily temperature between snowmelt and flowering as the average daily air temperature from the date of snowmelt through the average date of flowering for each species and year. Finally, we examined the association between the timing of snowmelt and flowering in long-term monitoring plots by comparing the phenological niches of species to snowmelt timing for the subset of 13 sites that had recorded snowmelt dates over time.

Models also included the effect of mean site-level summer temperatures (June-Aug) from 1981-2000 as an additional predictor variable of species phenological responses, since a previous synthesis found that flowering dates of species from colder tundra sites were more sensitive to changes in temperature than those from warmer sites. Mean monthly temperatures for sites were obtained from local weather stations when available. If no long-term (1981–2010) weather data were available near sites, then mean monthly temperatures were estimated using 0.5° gridded temperature data from the Climate Research Unit (CRU) (Supplementary Table 1). Temperatures and phenological niches were mean-centered by site for all species for long-term monitoring plot data. Plot within site, and year within site, were included as random variables. We also tested for the interaction between phenological niche and temperature.

In total, the analyses of FFDs with summer temperature windows or mean June temperatures as predictor variables included 14,324 observations from 318 unique site by species combinations at 19 sites. The analyses of FFDs with snowmelt date included 9,918 observations from 141 unique site by species combinations at 13 sites, and the analyses of FFDs using average daily temperatures included 9,713 observations from 143 unique site by
species combinations at 11 sites. The analyses of LFDs with summer temperature windows or
mean June temperatures as predictor variables included 9,226 observations from 88 unique
site by species combinations at 11 sites. The analyses of LFDs with snowmelt date included
7,661 observations from 80 unique site by species combinations at 11 sites, and the analyses
of LFDs using average daily temperatures included 7,341 observations from 74 unique site by
species combinations at 9 sites.

Effects of phenological niches on the temperature sensitivity of flowering in warming
experiments

We examined observations from warming experiments that utilized open-top
chambers (OTCs) to investigate how experimental warming influenced the flowering dates of
species with different phenological niches. In the warming experiments, plots were warmed
with ca. 1 m² fiberglass or polycarbonate OTCs, in either cone or hexagonal shapes, that
increased air temperature by 0.5-3 ºC \(^{67,70–72}\), Supplementary Table 3). The OTCs were placed
on plots either only over the summer, or left on plots year-round, depending on the site
(Supplementary Table S3).

To examine how the phenological niche of a species influenced its phenological
sensitivity to experimental warming, we first calculated the average difference in the timing of
phenological events (either FFD or LFD) between control and experimentally warmed plots at
each site and year for every species that occurred in both treatments. Then the phenological
niches of each species were compared to the difference in the number of days between the
FFD or the LFD in experimentally warmed and control plots for each species, site, and year
combination. Mean site-level summer temperature was not included as a predictor variable in
the warming experiment analyses because the amount of experimental warming differed
between experiments at different sites (Supplementary Table 3). We also examined how
differences in the amount of warming in different warming experiments may have altered
results by calculating the difference in the number of days between the FFDs or the LFDs in experimentally warmed and control plots divided the mean number of degrees of warming reported for chambers at each site or subsite within site (Supplementary Table 3) to get an estimate of the change in flowering date per °C of warming.

In total, the analyses of FFDs in warming experiments included 1219 flowering observations from 164 unique site by species combinations at 16 sites. Analyses of LFDs in warming experiments included 743 observations from 96 unique site by species combinations at 11 sites.

**Statistical analyses of effects of phenological niches on sensitivity of flowering**

To statistically analyze phenological observations over the different numbers of sites, years of observations, and species, we used Bayesian hierarchical modeling. This approach allowed for estimation of the uncertainties of phenological responses among sites, plots, years, and species, and the incorporation of these uncertainties in the final correlation of phenological niche and phenological responses per species per site 73.

For data from long-term monitoring plots, we used two-level regression models. At the lower level, we estimated phenological sensitivities by relating the date of phenological events (FFD or LFD) to temperature or snowmelt date. At the higher (species-) level, we related species’ phenological sensitivities to their phenological niches. For data from warming experiments, the difference (in days) of FFD or LFD between warmed and control plots was directly included as a response variable in the species-level regression.

We fit Bayesian models using the program Stan 74, which was accessed using the package Rstan 75 in the statistical program R 3.2.2 76. Each model was run with 2 chains of 20,000 iterations, using Hamiltonian Monte Carlo (HMC) sampling. We used flat priors for all parameter estimates. Full model details and code are included in S7. We checked for convergence of chains for all parameters both visually with trace plots and with the Gelman–
Rubin convergence statistic. Trace plots showed that chains mixed well and converged to stationary distributions for all parameter estimates. Gelman–Rubin convergence statistics for parameter estimates of all models were < 1.02.

Duration of flowering season

To test for a contraction of community-level flowering seasons in association with warmer summers, we conducted analyses that only included sites with FFDs and LFDs for four or more species over 10 or more years. This limited analyses to the six Arctic sites with long-term monitoring data: Alexandra Fiord, Atqasuk, Utqiagvik, Daring Lake, Toolik Lake, and Zackenberg. Flower count or peak flowering data were not available for all sites, so we used a proxy for the community flowering season calculated as the number of days between the average FFD of the earliest flowering species at a site per year and the average LFD of the latest flowering species at a site per year. We used the earliest and latest flowering species in each year to avoid any bias caused by uneven shifts in flowering times among species. Although changes in first and last flowering dates are not always representative of changes over the entire flowering season, we believe our proxy can provide an estimate of how the length of the flowering season may change with future warming. Additionally, a previous synthesis found that reproductive phenological events within the same species are highly correlated.

We compared this proxy for the duration of the community-level flowering season to the average June-July temperature at a site per year using a Bayesian hierarchical modeling approach. We mean-centered both flowering season length and average June-July temperatures for each site so we could compare the change in community-level flowering seasons with the change in June-July temperatures across sites. Because all sites chosen for these analyses had relatively long records of phenological measurements (>10 years), we also examined if flowering season length or June-July temperatures have changed significantly.
over time. We analyzed associations between community flowering season length and
summer temperature and time with a Bayesian hierarchical model using mean-centered June-
July temperature as the predictor variable for the temperature sensitivity models and year as
the predictor variable for the temporal change models and an intercept and slope that varied
by site. We also examined whether mean June-July temperatures changed over time using the
same models with year as the predictor variable. Full model details and code are included in
S7.

**Data Availability Statement**

The data that support the findings of this study have been archived at the Polar Data Catalogue (data
has been submitted to the Polar data catalogue - CCIN reference number 12961 -DOI will be updated
when data is approved).

Figure Legends

**Fig. 1.** Conceptual diagram showing how warmer summer temperatures may shorten the length of the flowering season in tundra ecosystems. If the phenology of early-flowering plant species is influenced primarily by photoperiod or the timing of snowmelt and does not respond appreciably to warmer summer temperatures, but the phenology of late-flowering species is mostly dependent on accumulated heat sums over the growing season, and does shift earlier with warmer summers, then there may be a contraction of the overall flowering season during warmer years.

**Fig. 2.** Map of long-term observational and experimental warming studies. Site names are listed in order from the site with the coldest (2.8 °C) to the site with the warmest (11.9 °C) summer temperatures (June-Aug. for northern hemisphere sites, Dec-Feb. for the southern hemisphere site, Supplementary Fig. 1). Site symbols shown on the map correspond to symbols and colors in Figs. 3-4. Asterisks indicate sites used in community flowering season analyses.

**Fig. 3.** Temperature sensitivity of first flowering dates (FFDs) was greater for late- versus early-flowering species. Relationships are shown between phenological niches of species and sensitivities of FFDs to (a) mean monthly temperature until flowering (b) mean June temperature (c) mean daily temperature between the snowmelt and flowering, and (d) the date of snowmelt. Points represent the estimated temperature sensitivities for each species at each site, and vertical gray lines span the 95% credible intervals for each species-by-site level estimate. Colors and symbols correspond to site names in Fig. 2. The ‘phenological niche’ is the average flowering date of a species compared to the site-level mean-flowering date of all species at a site. Solid black lines denote significant hierarchical model slopes, dashed black lines indicate non-significant model slopes, and the horizontal grey line denotes the zero line. Hierarchical model slopes and 95% credible intervals (CIs) are listed in the bottom left of each graph. The phenological niches significantly predict phenological responses (at the 5% level) if the 95% credible intervals do not overlap zero.

**Fig. 4.** The change in first flowering dates (FFDs) in response to experimental warming was greater for late- versus early-flowering species. Relationships are shown between phenological niches of species and timing of (a) FFDs and (b) Last flowering dates (LFDs) in experimentally warmed plots compared to control plots. Points represent the estimated temperature sensitivities for each species at each site, and vertical gray lines span the 95% credible intervals for each species-by-site level estimate. Colors and symbols correspond to site names in Fig. 2. The ‘phenological niche’ is the average flowering date of a species compared to the site-level mean-flowering date of all species at a site. Solid black lines denote significant hierarchical model slopes, dashed black lines indicate non-significant model slopes, and the horizontal grey line denotes the zero line. Hierarchical model slopes and 95% credible intervals (CIs) are listed in the bottom left of each graph. The phenological niches significantly predict phenological responses (at the 5% level) if the 95% credible intervals do not overlap zero.

**Fig. 5.** Warming was related to the change in the duration of the flowering season over time at sites across the tundra biome. (a) Difference in the duration of the community level flowering season compared to the difference in mean June-July temperatures from site averages. (b) Change in the duration of the community level flowering season over time. (c) Yearly June-July temperature over time. Flowering season length and average June-July temperatures were mean-centered for each site so they could be compared across sites. Points represent the change in the community-level flowering season per site and year. Solid black lines denote significant hierarchical model slopes, and dashed black lines indicate non-significant model slopes. Colored bands show the 95% credible intervals for site-level slopes. Hierarchical model slopes and 95% credible intervals (CIs) are listed in the bottom left of each graph.
Warmer summers

Date of Flowering

Flowering season

Late-flowering species

Early-flowering species

Warmer summers
Change in FFD with summer temp.

- Slope = -0.08
- CI = (-0.12, -0.04)

Change in FFD with June temp.

- Slope = -0.06
- CI = (-0.09, -0.03)

Change in FFD with daily mean temp.

- Slope = -0.04
- CI = (-0.10, -0.0006)

Change in FFD with snowmelt date

- Slope = 0.0004
- CI = (-0.0070, 0.0009)
Slope = −0.06
CI = (−0.09, −0.03)

Slope = −0.04
CI = (−0.15, 0.02)
